Spontaneous hemorrhage into a pituitary adenoma, termed *pituitary apoplexy*, is a rare life-threatening medical emergency. Signs and symptoms include acute visual changes, severe headache, neck stiffness, hypotension, loss of consciousness, and coma. These symptoms result from: (1) leakage of blood and necrotic material into the subarachnoid space, (2) acute hypopituitarism, and (3) a rapidly expanding hemorrhagic intrasellar mass that compresses the optic chiasm, cranial nerves, or hypothalamus and internal carotid arteries. Apoplexy may lead to severe hypoglycemia, hypotension, CNS hemorrhage, and death. Nevertheless, with rapid diagnosis and management, the outcome of patients with pituitary apoplexy is excellent (Singh, 2015). Glucocorticoid replacement is a mainstay of supportive treatment. Surgical decompression is frequently but not invariably required.

Pregnancy and Pituitary Adenomas

The pituitary gland enlarges during pregnancy, primarily due to hypertrophy and hyperplasia of the lactotropes in response to elevated serum estrogen levels. Although the tumor can enlarge during pregnancy, clinical experience shows this risk is small. Tumor growth leading to significant symptoms complicates approximately 2 percent of microadenomas and 21 percent of untreated macroadenomas (Molitch, 2015). However, because significant expansion may lead to headaches or compression of the optic chiasm and blindness, visual field testing is considered in every trimester for women with macroadenomas. Although dopamine agonist therapy has been associated with a higher risk of spontaneous miscarriages, preterm deliveries, and congenital malformation, data overall suggest that most patients can be treated safely. Nevertheless, most experts advise that dopamine agonist therapy be discontinued during pregnancy when possible.

Treatment of Hyperprolactinemia and Pituitary Adenomas

Dopamine agonists may be considered in any patient with hyperprolactinemia in whom a large non-prolactin-producing tumor or other cause of hyperprolactinemia has been excluded. In this situation, it is likely that the patient has an undetectable microadenoma. However, the incidence of this is decreasing with the advent of highly sensitive MR imaging.

Most pituitary tumors grow slowly, and many cease growth after attaining a certain size. Thus, asymptomatic patients with a microprolactinoma may be managed conservatively with serial MR imaging and serum PRL levels every 1 to 2 years. The risk of progression to a macroadenoma is <10 percent (Schlechte, 1989). These women should be followed for even mild changes in menstrual cyclicity, as they are at risk for developing hypoestrogenism.

When tumors of any size are associated with amenorrhea or galactorrhea, therapy is considered (Fig. 16-22). Neurosurgical evaluation is mandatory when visual field defects or severe headaches are present. In general, first-line treatment is medical for both micro- and macroadenomas. Specifically, women should receive a dopamine agonist such as the nonspecific dopamine-receptor agonist bromocriptine (Parlodel) or the dopamine-receptor type 2 agonist cabergoline (Dostinex).

These dopamine agonists decrease PRL secretion and shrink tumor size. However, bromocriptine treatment is

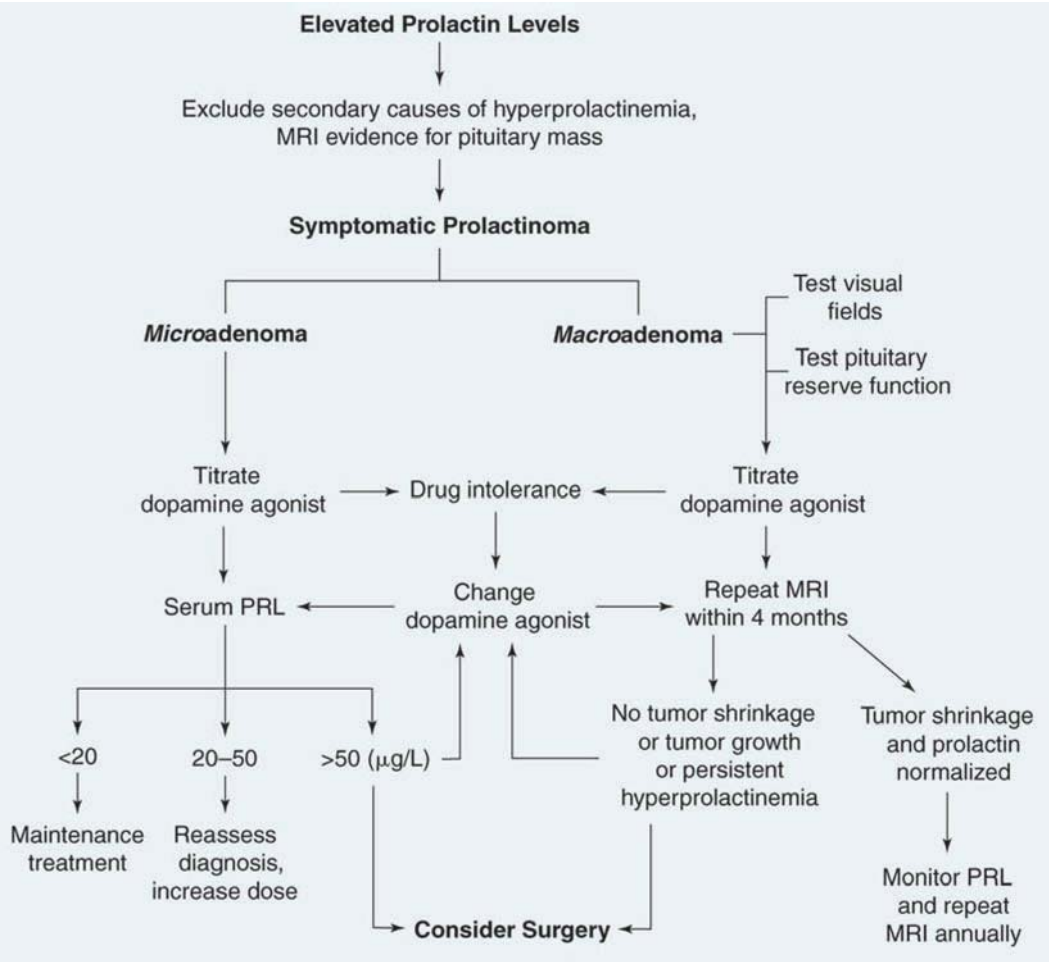

FIGURE 16-22 Algorithm describing the evaluation and treatment of pituitary adenomas. MRI = magnetic resonance imaging; PRL = prolactin. (Redrawn with permission from Melmed S, Jameson JL: Pituitary tumor syndromes. In Jameson JL, Fauci AS, Kasper DL, et al (eds): Harrison's Principles of Internal Medicine, 20th ed. New York, McGraw-Hill Education, 2018.)

associated with several common side effects, including headache, postural hypotension, blurry vision, drowsiness, and leg cramps. Most of these are attributable to activation of type 1 dopamine receptors. Due to its receptor specificity, cabergoline treatment is generally better tolerated than bromocriptine. Cabergoline also has a longer half-life, allowing once- or twice-weekly dosing. This compares favorably against the multiple daily doses that may be required for bromocriptine. Typical initial cabergoline dosages are 0.25 mg orally twice weekly. Cabergoline has been found to be more effective than bromocriptine in normalizing PRL levels (dos Santos Nunes, 2011). Nevertheless, cabergoline can be prohibitively expensive. Most patients can tolerate bromocriptine if started at a low dose—½ tab or 0.125 mg—each night to minimize associated nausea and dizziness. This dose can be slowly increased to three times daily as tolerated. Reliable measurement of posttreatment serum PRL levels can be obtained 1 month following a steady medication dose.

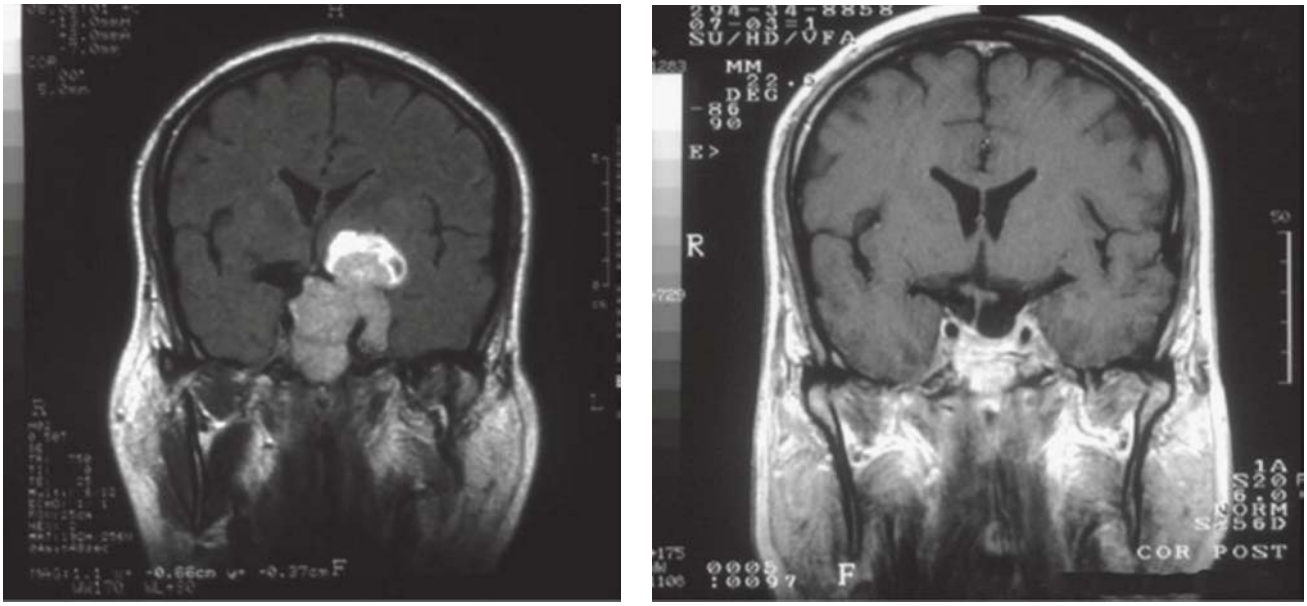
Neurosurgery is required for refractory tumors or those causing acutely worsening symptoms. The pituitary is approached through a transsphenoidal route whenever possible (Fig. 16-23). Complications of surgery, although rare, include intraoperative hemorrhage, a cerebrospinal fluid leak causing rhinorrhea, diabetes insipidus, damage to other pituitary cell types, and meningitis (Miller, 2014).

Radiation therapy may be used for patients with surgically nonresectable, persistent, or aggressive tumors. The radiation dose necessary to stop tumor growth is lower than the dose necessary to achieve normalization of hormonal hypersecretion. More precise stereotactic radiosurgical approaches such as the gamma knife have improved radiation-beam focus, which significantly lessens local tissue damage and improves patient tolerance. Risks include optic nerve damage and delayed hypopituitarism (Pashtan, 2014).

DISORDERS OF PEPTIDE AND STEROID HORMONES IN REPRODUCTION

Clinical disorders may result from mutations in genes affecting hormone biosynthesis or the receptors that transduce the response. Both pituitary peptide and steroid hormones can be affected.

First, numerous mutations have been identified in the genes that encode the LH/CG and FSH receptors. Most of the identified mutations inactivate function. These produce gonadotropin



A B

FIGURE 16-23 Magnetic resonance images of a pituitary macroadenoma before and after surgical resection. **A.** Preoperative coronal image reveals tumor measuring greater than 10 mm. **B.** Postoperative coronal image of the same patient following tumor excision.

resistance of variable severity that ranges from primary amenorrhea to oligomenorrhea and infertility (Latronico, 2013). Receptor mutations that activate function appear to be rare. However, a constitutively active LH/CG mutant receptor does cause a familial gonadotropin-independent precocious puberty that is limited to males (Ulloa-Aguirre, 2014). Although uncommon, mutations in the genes encoding the gonadotropin hormones themselves result in varying degrees of hypogonadism (Basciani, 2012; Kottler, 2010).

Second, gene mutation can lead to decreased function in steroid receptors. The best known is androgen insensitivity syndrome (AIS). With AIS, inactivating mutations in the androgen receptor impair the ability to respond to androgens. As a result, these 46,XY individuals haven female external genitalia and scant to absent pubic and axillary hair. However, their testes do produce antimüllerian hormone, their müllerian ducts fail to develop, and thus a blind-ending vaginal pouch without uterus or fallopian tubes results. Breasts develop in response to estrogens obtained from aromatization of circulating testicular steroids (Tadokoro-Cucaro, 2014). Phenotypes of AIS are further described in Chapter 19 (p. 414).

Last, mutations in the enzymes necessary for steroidogenesis create broad clinical effects. Phenotypes depend on the location and severity of the resulting enzymatic deficiency within the steroidogenic pathway (Miller, 2011). The most common is congenital adrenal hyperplasia (CAH), typically due to a 21-hydroxylase deficiency. With severe enzymatic deficiency, affected patients have life-threatening salt wasting and female-to-male disorder of sexual differentiation (46,XX DSD). A less severe mutation may lead to "simple virilizing CAH," in which elevated androgen levels are the primary hormonal abnormality (Auchus, 2015). The mildest abnormalities present as "nonclassic," "late-onset," or "adult-onset" CAH. In these patients, activation of the adrenal axis at puberty increases steroidogenesis and unmasks a mild 21-hydroxylase deficiency. Excess androgen provides negative feedback to GnRH receptors in the hypothalamus. These patients often have hirsutism, acne, and anovulation. Thus, late-onset CAH may mimic PCOS (McCann-Crosby, 2014). Additional discussion of CAH and disorders of sexual differentiation is found in Chapter 19 (p. 415).

ESTROGENS AND PROGESTINS IN CLINICAL PRACTICE

In gynecology, estrogen and/or progestins are used for contraception and for treating abnormal uterine bleeding, endometriosis, leiomyomas, PCOS, and menopausal symptoms. Specific uses are found in the respective chapters on these topics. Of the various estrogen and progestin preparations, each differs in its biologic efficacy, and clinicians should understand these differences.

Estrogens

Classic estrogens are C18 steroid compounds containing a phenolic ring (Fig. 16-24). This group contains the natural estrogens—estradiol, estrone, estriol—and their derivatives. It also contains conjugated equine estrogens (CEE). The predominant synthetic C18 estrogen is ethinyl estradiol, which is the estrogen present in most combination oral contraceptives. Synthetic nonsteroidal estrogens include diethylstilbestrol (DES) and selective estrogen-receptor modulators. Despite their variation from the classic steroid ring shape, nonsteroidal estrogens are still able to bind to the estrogen receptor.

Of the natural estrogens, 17β-estradiol is the most potent and is followed by estrone and then estriol. In comparing some pharmacologically used estrogens, ethinyl estradiol, a derivative of 17β-estradiol, is approximately 100 to 1000 times more

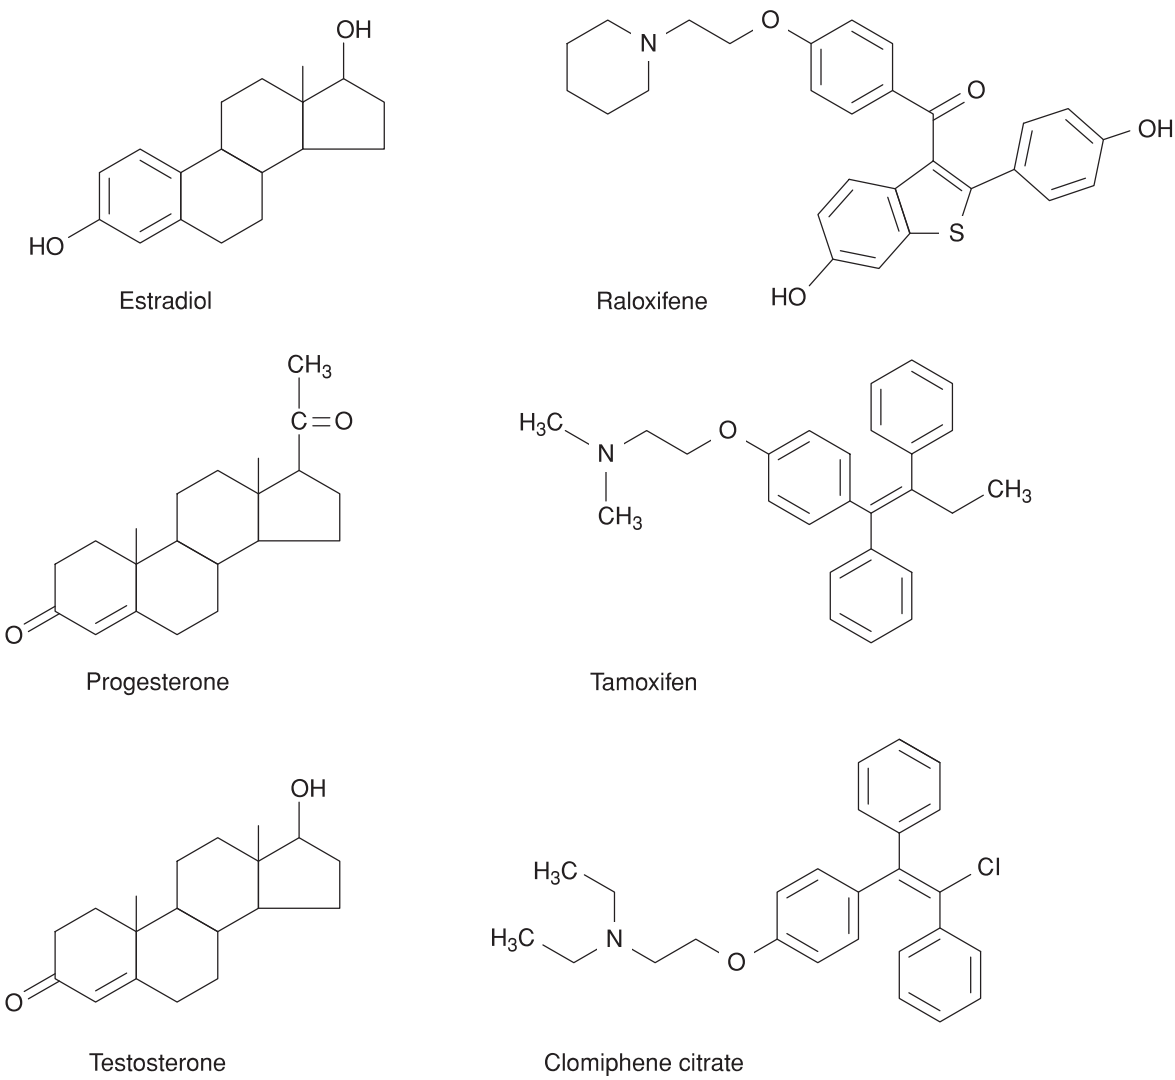


FIGURE 16-24 Chemical structures of important sex steroids and selective estrogen-receptor modulators.

potent on a per-weight basis than either micronized estradiol or CEE in increasing SHBG levels, which is one marker of estrogen potency (Kuhl, 2005; Mashchak, 1982).

Progestogens

Although not codified, *progestogens* include natural progesterone and synthetic progestogens, which are called *progestins*. Only progesterone can maintain human pregnancy. Progestins can be classified as derivatives of either 19-norprogesterone or 19-nortestosterone (Kuhl, 2005). Of the 19-norprogesterones, the most commonly used are medroxyprogesterone acetate and megestrol acetate.

Most progestins used in contraceptives are derived from 19-nortestosterone. These are commonly grouped as first generation (norethindrone), second generation (levonorgestrel, norgestrel), or third generation (desogestrel, norgestimate). As described in Chapter 5 (p. 121), each generation was designed to have progressively less androgenic effects. The fourth-generation progestin drospirenone is unique in that it is derived from spironolactone. Although it has no androgenic activity, drospirenone's affinity for the mineralocorticoid receptor is approximately five times that of aldosterone. This explains its diuretic action.

Selective Steroid-Receptor Modulators

As indicated by their names, these synthetic compounds bind to their target receptors and exert tissue-specific effects, acting as agonists in some tissues and antagonists in others (Table 16-7). The variable activity among the selective estrogen-receptor modulators (SERMs) is attributed to differences at the molecular level. Each SERM binds to an estrogen receptor to generate a unique molecular conformation that affects the interaction of the complex with transcriptional cofactors and gene promoter regions. The response is also modified by the relative expression of ERα and ERβ receptors in the target tissue. The hormonal milieu also may affect the agonist–antagonist profile of a specific SERM. For example, a SERM may act as an estrogen agonist in a low-estrogen state, such as menopause, but as a competitive antagonist in a patient with high circulating estradiol levels.

Development of new SERMs with specific agonist/antagonist profiles continues as an active research topic. The SERM ospemifene (Osphena) may have favorable characteristics for

TABLE 16-7. Agonist or Antagonist Effects of Estradiol and Selected SERMs

Drug	Breast	Bone	Lipids	Endometrium
Tamoxifen	Antagonist	Agonist	Agonist	Agonist

Ospemifene	Neutral	Agonist	Neutral	Partial agonist
Bazedoxifene	Antagonist	Agonist	Agonist	Antagonist
Estradiol	Agonist	Agonist	Agonist	Agonist

SERM = selective estrogen-receptor modulator.
Compiled from Archer, 2015; Miller, 2008; Ylikorkala, 2003.

long-term relief of genitourinary syndrome of menopause (Archer, 2015). The SERM bazedoxifene is combined with CEE and marketed as Duavee. This coupled approach yields a drug group categorized as *tissue-selective estrogen complexes (TSECs)*. The goal of TSECs is to provide estrogen agonist/antagonist profiles that optimize clinical efficacy and safety.

Selective progesterone-receptor modulators (SPRMs) are available for emergency contraception and in some countries for treatment of abnormal uterine bleeding, leiomyomas, and endometriosis (Wagenfeld, 2016). Of these, ulipristal acetate has been linked to possible severe liver damage and is discussed in Chapter 9 (p. 208).

Selective androgen-receptor modulators (SARMs) also are under investigation for osteopenia treatment and decreased libido. Ideally, these will avoid the virilizing effects of testosterone treatment (Solomon, 2019).

As indicated by the preceding discussion, the agonist–antagonist effect of a steroid hormone is inextricably related to the clinical tissue of interest. This concept is most frequently discussed in terms of selective steroid-receptor modulators, but all steroid hormones within a class exert differences in their pattern of action across tissues. As a result, when a steroid is chosen for treatment, each clinical end point should be considered individually.

Steroid Hormone Potency

The efficacy of estrogen and progestogen treatments is altered by numerous factors. These include: (1) receptor binding affinity, (2) formulation, (3) administration route, (4) metabolism, and (5) affinity for binding globulins. First, even small chemical modifications can substantially alter the biologic effects of steroid preparations. For example, the progestins in clinical use all exert progestogenic effects but may also act as weak androgens, antiandrogens, glucocorticoids, or antimineralocorticoids. These differences are likely explained by variations in binding affinity for each of these steroid receptors (Table 16-8) (Wiegratz, 2004).

Second, estrogens and progestogens can be administered as oral, transdermal, vaginal, or intramuscular preparations, among others. The choice of carrier molecule affects hormone bioavailability. For example, although crystalline progesterone is poorly absorbed via the intestine, dispersion of the progesterone into small particles (micronization) markedly increases surface area and uptake.

Third, oral medications pass through the intestine and the liver prior to systemic dissemination. As these tissues are sites for steroid metabolism, oral medications and their levels may be significantly altered prior to reaching their target organs. As an example, the bioavailability of orally administered micronized

TABLE 16-8. Relative Binding Affinities of Steroid Receptors and SHBG to Progestogens

Progestogen	PR	AR	ER	GR	MR	SHBG	CBG
Progesterone	50	0	0	10	100	0	36
MPA	115	5	0	29	160	0	0
Levonorgestrel	150	45	0	1	75	50	0
Etonogestrel	150	20	0	14	0	15	0
Norgestimate	15	0	0	1	0	0	0
Dienogest	5	10	0	1	0	0	0
Drospirenone	35	65	0	6	230	0	0

AR = androgen receptor; CBG = cortisol-binding globulin; ER = estrogen receptor; GR = glucocorticoid receptor; MPA = medroxyprogesterone acetate; MR = mineralocorticoid receptor; PR = progesterone receptor; SHBG = sex hormone–binding globulin.

TABLE 16-9. Relative Potency of Various Estrogens Concerning Clinical and Metabolic Parameters[a]

	Suppression of:		Increase Serum Levels of:			
Estrogen	Hot flashes	FSH	HDL	SHBG	CBG	Angiotensinogen
Estradiol-17β	100	100	100	100	100	
Estriol	30	20				
CEE	120	110	150	300	150	500
Ethinyl estradiol	12,000	12,000	40,000	50,000	60,000	35,000

[a]The values are estimated on a weight basis.
CBG = cortisol-binding globulin; CEE = conjugated equine estrogens; FSH = follicle-stimulating hormone; HDL = high-density lipoprotein; SHBG = sex hormone–binding globulin.

progesterone is <10 percent and compares poorly with the estimated 50- to 70-percent bioavailability for norethindrone and 100-percent level for levonorgestrel. This difference stems from a high level of "first pass" metabolism of micronized progesterone but not of these modified progestins (Stanczyk, 2002). As another example, the half-life of ethinyl estradiol is greatly extended relative to that of unconjugated estradiol by the presence of the ethinyl group, which impairs metabolism.

Absorption and metabolism rates may differ between individuals due to inherited or acquired differences in liver, intestinal, and renal function (Kuhl, 2005). Local metabolism also will lower steroid efficacy and can include conversion between steroids (for example, androgens to estrogens by aromatase) or within a steroid type (for example, estradiol to the weaker estrone). Diet, alcohol consumption, cigarette smoking, exercise, and stress all have been postulated to alter steroid metabolism. Thyroid disease also affects drug metabolism rates. Medications that elevate hepatic enzyme activity may increase estrogen metabolism. Best understood is the ability of some antiepileptic drugs to decrease estrogen-containing contraceptive efficacy, which is described in Chapter 5 (p. 126) (O'Brien, 2010).

Last, steroid potency depends on affinity for the various carrier proteins produced by the liver. Only unbound hormone, and to a much lesser extent the amount bound to albumin or cortisol-binding globulin (CBG), is functionally active. Steroid bound to SHBG is considered inactive. Ethinyl estradiol is bound nearly exclusively to albumin, and this enhances its bioavailability (Barnes, 2007). As shown in Table 16-8, significant differences in carrier binding are also observed for progestogens (Wiegratz, 2004).

Importantly, hormonal status affects expression of carrier proteins. Specifically, estrogens and thyroid hormone stimulate SHBG, whereas androgens blunt serum SHBG levels. To add further complexity, target cells are thought to secrete SHBG, which then acts locally as a membrane receptor to stimulate cyclic adenosine monophosphate (cAMP) intracellular signaling pathways (Rosner, 2010).

Steroid Bioassays

A limited number of studies have used bioassays to evaluate the efficacy of pharmacologic estrogens in women using clinical, endocrinologic, and metabolic parameters (Table 16-9) (Kuhl, 2005). As seen in animal studies, different preparations vary markedly in their potency. Of note, estrogens also demonstrate differences in terms of their tissue specificity. For example, 17β-estradiol and CEE suppress pituitary FSH to a similar extent, whereas CEE is a more potent stimulator of liver SHBG production. Data suggest that these distinctions are likely important to assess the physiologic effects of pharmacologic, herbal, and environmental sources of steroids on health.

CHAPTER 17

Amenorrhea

NORMAL MENSTRUAL CYCLE 371
CLASSIFICATION SYSTEM 372
ANATOMIC DISORDERS 372
HYPERGONADOTROPIC HYPOGONADISM 375
HYPOGONADOTROPIC HYPOGONADISM 377
EUGONADOTROPIC AMENORRHEA 381
EVALUATION 382
TREATMENT 385
REFERENCES 386

Evaluation and management of a patient with amenorrhea is common in gynecology, and the prevalence of pathologic amenorrhea ranges from 3 to 4 percent in reproductive-aged populations (Bachmann, 1982). Amenorrhea has classically been defined as primary (no prior menses) or secondary (cessation of menses). Although this distinction does suggest a relative likelihood of finding a particular diagnosis, the approach to diagnosis and treatment is similar for either presentation (Tables 17-1 and 17-2). Of course, amenorrhea is a normal state prior to puberty, during pregnancy and lactation, and following menopause. Evaluation is considered for an adolescent: (1) who has not menstruated by age 15 or within 3 years of thelarche or (2) has not menstruated by age 14 and shows signs of hirsutism, excessive exercise, or eating disorder (American College of Obstetrician and Gynecologists, 2017d). Secondary amenorrhea for 3 months or fewer than nine cycles per year also is investigated (American Society for Reproductive Medicine, 2008; Klein, 2013). In some circumstances, testing reasonably may be initiated despite the absence of these strict criteria. Examples include a patient with the stigmata of Turner syndrome, obvious virilization, or a history of uterine curettage. An evaluation for delayed puberty is also considered before the ages listed above if the patient or her parents are concerned.

NORMAL MENSTRUAL CYCLE

A differential diagnosis for amenorrhea can be constructed based on requirements for normal menses. Ovarian function in a normal menstrual cycle is divided into the follicular phase (preovulatory), ovulation, and luteal phase (postovulatory). Endometrial characteristics are partitioned into the proliferative phase (preovulatory) and secretory phase (postovulatory).

Generation of a cyclic, controlled pattern of uterine bleeding requires precise temporal and quantitative regulation of several reproductive hormones (Chap. 16, p. 348). First, the hypothalamic-pituitary-ovarian axis must be functional. The hypothalamus releases pulses of gonadotropin-releasing hormone (GnRH) into the hypophyseal portal circulation at defined frequencies and amplitude. GnRH stimulates the synthesis and secretion of the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the gonadotrope cells of the anterior pituitary gland. These gonadotropins enter the peripheral circulation and act on the ovary to stimulate both follicular development and ovarian hormone production. These ovarian hormones include estrogens, progesterone, and androgens. Gonadal steroids are typically inhibitory at both the pituitary and the hypothalamus. Development of a mature follicle, however, creates a rapid rise in estrogen levels, which instead

TABLE 17-1. Primary Amenorrhea: Frequency of Etiologies

Presentation	Frequency (%)
Hypergonadotropic hypogonadism	43
45,X and variants	27
46,XX	14
46,XY	2
Eugonadism	30
Müllerian agenesis	15
Vaginal septum	3
Imperforate hymen	1
AIS	1
PCOS	7
CAH	1
Cushing and thyroid disease	2
Low FSH without breast development	27
Constitutional delay	14
GnRH deficiency	5
Other CNS disease	1
Pituitary disease	5
Eating disorders, stress, excess exercise	2

AIS = androgen insensitivity syndrome; CAH = congenital adrenal hyperplasia; CNS = central nervous system; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; PCOS = polycystic ovarian syndrome. Adapted from Reindollar, 1981, with permission.

TABLE 17-2. Secondary Amenorrhea: Frequency of Etiologies[a]

Etiology	Frequency (%)
Low or normal FSH level: various	67.5
Eating disorders, stress, excess exercise	15.5
Nonspecific hypothalamic	18
Chronic anovulation (PCOS)	28
Hypothyroidism	1.5
Cushing syndrome	1
Pituitary tumor/empty sella	2
Sheehan syndrome	1.5
High FSH level: gonadal failure	10.5
46,XX	10
Abnormal karyotype	0.5
High prolactin level	13
Anatomic	7
Asherman syndrome	7
Hyperandrogenic states	2
Nonclassic CAH	0.5
Ovarian tumor	1
Undiagnosed	0.5

[a]Excluding pregnancy diagnoses.
CAH = congenital adrenal hyperplasia; FSH = follicle-stimulating hormone; PCOS = polycystic ovarian syndrome.
Adapted from Reindollar, 1986, with permission.

act positively to generate an LH release surge. This surge is essential for ovulation.

Following ovulation, LH stimulates luteinization of the granulosa and theca cells, which had surrounded the mature oocyte, to form the corpus luteum. The corpus luteum continues to produce estrogen but also secretes high levels of progesterone. The thickened, proliferative endometrial lining produced by high circulating estrogen levels during the follicular phase is now converted to a secretory pattern by this luteal progesterone. If pregnancy occurs, the corpus luteum is "rescued" by human chorionic gonadotropin (hCG) secreted from early placental trophoblast. Structurally similar to LH, hCG binds to and signals via the same receptor and assumes the role of corpus luteum support during early pregnancy. If pregnancy does not occur, then progesterone and estrogen secretion ceases, the corpus luteum regresses, and the endometrium sloughs. The pattern of this "progesterone withdrawal bleed" varies in duration and amount among women but is relatively constant across cycles for a given individual.

Amenorrhea may follow disruption of this choreographed communication. However, menses may be absent even with normal cyclic hormonal changes due to anatomic abnormalities. The endometrium must be able to respond normally to hormonal stimulation, and the cervix, vagina, and introitus must be present and patent.

CLASSIFICATION SYSTEM

Numerous classification systems for the diagnosis of amenorrhea have been developed, and all have their strengths and weaknesses. One useful scheme is outlined in Table 17-3. This system divides causes of amenorrhea into anatomic versus hormonal etiologies, with further division into congenital and acquired disorders.

As described above, normal menses require adequate ovarian production of steroid hormones. Decreased ovarian function (hypogonadism) may result either from a lack of stimulation by the gonadotropins (*hypo*gonadotropic hypogonadism) or from primary failure of the ovary (*hyper*gonadotropic hypogonadism) (Table 17-4). Several disorders are associated with relatively normal LH and FSH levels (*eu*gonadotropic), however, appropriate cyclicity is lost.

ANATOMIC DISORDERS

Inherited Disorders

Anatomic abnormalities causing amenorrhea can broadly be viewed as either inherited or acquired disorders of the outflow tract (uterus, cervix, vagina, and introitus). Of these two, inherited causes will generally present at menarche in adolescents. Pelvic anatomy is abnormal in approximately 15 percent of women with primary amenorrhea (American Society for Reproductive Medicine, 2008). Figure 17-1 depicts the range of anatomic defects that may present with amenorrhea. Various classification schemes for congenital genital tract anomalies have been developed. Of these, the American Society for Reproductive Medicine (ASRM) classification is longstanding and likely the most used (American Fertility Society, 1988). However, the consensus classification more recently developed by the European Society of Human Reproduction and Embryology (ESHRE) and the European Society for Gynaecological Endoscopy (ESGE) is gaining popularity (Grimbizis, 2013). These are additionally discussed in Chapter 19 (p. 419).

Lower Outflow Tract Obstruction

Amenorrhea is associated with imperforate hymen (1 in 2000 women), a complete transverse vaginal septum (1 in 70,000

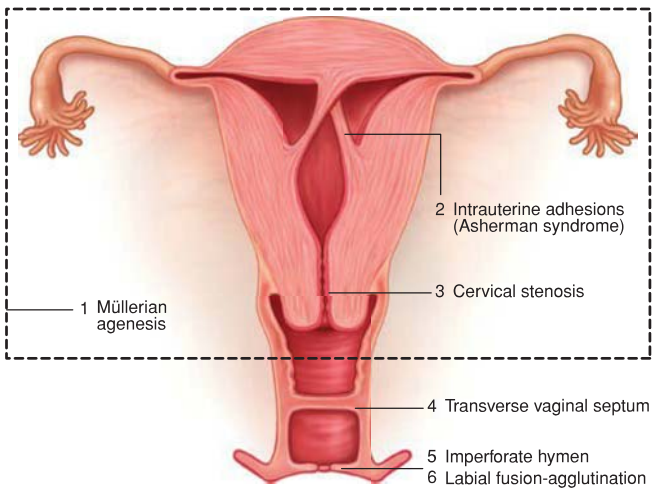

FIGURE 17-1 Anatomic defects that may lead to amenorrhea. Müllerian agenesis results in an absence of the upper reproductive tract structures contain within the dash-lined box.

TABLE 17-3. Classification Scheme for Nonphysiologic Amenorrhea

Anatomic

Congenital
- Müllerian agenesis (partial or complete)
- Vaginal septum
- Cervical atresia
- Imperforate hymen
- Complete androgen resistance

Acquired
- Intrauterine synechiae (Asherman syndrome)
- Cervical stenosis

Hormonal/Endocrinologic

Hypergonadotropic hypogonadism (POI)

Inherited
- Chromosomal (gonadal dysgenesis)
- Single-gene disorders

Acquired
- Infectious
- Autoimmune
- Iatrogenic (chemotherapy or radiation)
- Environmental
- Idiopathic

Hypogonadotropic hypogonadism

Disorders of the hypothalamus = hypothalamic amenorrhea

Inherited
- Idiopathic hypogonadotropic hypogonadism (IHH)
- Kallmann syndrome

Acquired
- Hypothalamic amenorrhea ("functional")
  - Eating disorders
  - Excessive exercise
  - Stress
- Destructive processes
  - Tumor
  - Radiation
  - Trauma
  - Infection
  - Infiltrative disease
- Pseudocyesis

Eugonadotropic amenorrhea

Inherited
- Polycystic ovarian syndrome
- Nonclassic congenital adrenal hyperplasia

Acquired
- Hyperprolactinemia
- Thyroid disease
- Cushing syndrome
- Acromegaly
- Ovarian tumors (steroid producing)

Hypogonadotropic hypogonadism (cont'd)

Disorders of the anterior pituitary gland

Inherited/congenital
- Pituitary hypoplasia

Acquired
- Adenoma
  - Prolactinoma
- Destructive processes
  - Macroadenoma
  - Metastases
  - Radiation
  - Trauma
  - Infarction (Sheehan syndrome)
  - Infiltrative disease

Chronic disease
- End-stage kidney disease
- Liver disease
- Malignancy
- Acquired immunodeficiency syndrome
- Malabsorption syndromes
- Drug abuse

POI = premature ovarian insufficiency.

TABLE 17-4. Categories of Amenorrhea Based on Gonadotropin and Estrogen Levels

Type of Hypogonadism	LH/FSH	Estrogen	Primary Defect
Hypergonadotropic	High	Low	Ovary
Hypogonadotropic	Low	Low	Hypothalamus/pituitary
Eugonadotropic	Normal[a]	Normal[a]	Varied

[a]Generally in normal range, but lack cyclicity.
FSH = follicle-stimulating hormone; LH = luteinizing hormone.

women), or isolated vaginal atresia (Banerjee, 1998; Parazzini, 1990). Also, although structurally normal, labia in some girls may be severely agglutinated and can lead to obstruction. Most with agglutination are treated early with topical estrogen and/or manual separation, and outflow obstruction is thereby avoided.

Patients with outflow obstruction have a 46,XX karyotype, female secondary sexual characteristics, and normal ovarian function. Thus, the amount of uterine bleeding is normal, but its normal path for egress is obstructed or absent. Patients may note moliminal symptoms, such as breast tenderness, food cravings, and mood changes, which are attributable to elevated progesterone levels. With inherited or acquired outflow obstruction, accumulation of blood behind the blockage frequently results in cyclic abdominal pain. Intrauterine trapping of fluid (hydrometra), pus (pyometra), or blood (hematometra) creates a soft, enlarged uterus. Similarly, the terms *hydrotrachelos*, *pyotrachelos*, and *hematotrachelos* define distention of the cervix, whereas *hydrocolpos*, *pyocolpos*, and *hematocolpos* describe distention of the vagina. These are seen with more distal obstructions. Importantly, in women with outflow blockage, an increase in retrograde menstruation places the patient at high risk for endometriosis development.

Müllerian Defects

During embryonic development, the müllerian ducts give rise to the upper vagina, cervix, uterine corpus, and fallopian tubes. Agenesis during these ducts' development may be partial or complete. Accordingly, amenorrhea may result from outflow obstruction or from a lack of endometrium in cases involving uterine agenesis. In complete müllerian agenesis, often called *Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome*, patients fail to develop any müllerian structures, and examination reveals only a vaginal dimple. With an incidence of 1 per 5000 females, MRKH ranks second only to gonadal dysgenesis as a cause of primary amenorrhea (Aittomaki, 2001; American College of Obstetricians and Gynecologists, 2018b). Research has begun to identify gene mutations that may contribute to this disorder (Fontana, 2017).

Importantly, complete müllerian agenesis may be confused with complete androgen insensitivity syndrome. In the latter condition, the patient has a 46,XY karyotype and functioning testes (Batista, 2018). However, underlying androgen receptor mutations prevent normal testosterone binding, normal male ductal system development, and virilization. These two syndromes are compared in Table 17-5 and discussed further in Chapter 19 (p. 421).

TABLE 17-5. Comparison of Müllerian Agenesis and Androgen Insensitivity Syndrome

Presentation	Müllerian Agenesis	Androgen Insensitivity
Inheritance pattern	Sporadic	X-linked recessive
Karyotype	46,XX	46,XY
Breast development	Yes	Yes
Axillary and pubic hair	Yes	No
Uterus	No	No
Gonad	Ovary	Testis
Testosterone	Female levels	Male levels
Associated anomalies	Yes	No

Acquired Disorders

Cervical Stenosis

Other abnormalities of the uterus that cause amenorrhea include cervical stenosis and extensive intrauterine adhesions. With stenosis, postoperative scarring and cervical os narrowing may follow dilatation and curettage (D & C), cervical conization, loop electrosurgical excision procedures, infection, and neoplasia. Severe atrophic or radiation changes are other sources. Stenosis involves the internal or external os, and symptoms in menstruating women include amenorrhea or abnormal bleeding, dysmenorrhea, and infertility. Management seeks to reopen the os and is discussed in Chapter 41 (p. 903).

Intrauterine Adhesions

Also known as *uterine synechiae* and, when symptomatic, as *Asherman syndrome*, the spectrum of scarring includes filmy adhesions, dense bands, or complete obliteration of the uterine cavity (Fig. 17-2). Normally, the endometrium is divided into a functional layer, which lines the endometrial cavity, and a basal

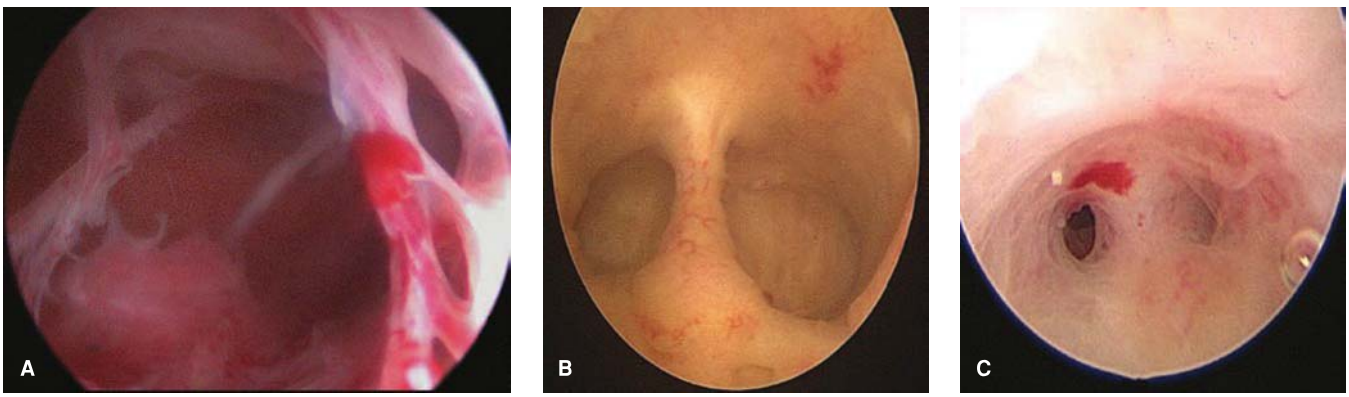

FIGURE 17-2 Hysteroscopic photographs of progressively dense intrauterine adhesions found with Asherman syndrome. **A.** Filmy. **B.** Dense. **C.** Nearly obliterating. (Reproduced with permission from Drs. David Rogers and Kevin Doody.)

layer, which regenerates the functional layer with each menstrual cycle. Destruction of the basal endometrium prevents endometrial thickening in response to ovarian steroids. Thus, no tissue is produced or subsequently sloughed when steroid hormone levels fall at the end of the luteal phase.

Endometrial damage may follow vigorous curettage, usually in association with postpartum hemorrhage, miscarriage, or elective abortion complicated by infection. In a series of 1856 women with Asherman syndrome, 88 percent followed postabortal or postpartum uterine curettage (Schenker, 1982). Risks for intrauterine adhesions rise with the number of D & Cs for spontaneous first-trimester abortion (Hooker, 2014). In one prospective study, the risk was 16 percent after a single termination. The rate rose to 32 percent and with progressively more dense adhesions observed following three or more procedures (Friedler, 1993).

Damage may also result from other uterine surgery, including metroplasty, myomectomy, or cesarean delivery, or from infection related to an intrauterine device. Although rare in the United States, tuberculous endometritis is a relatively common cause of Asherman syndrome in developing countries (Sharma, 2009). Of course, Asherman syndrome may also be an intentional outcome following uterine ablation for heavy menstrual bleeding.

Depending on the degree of scarring, patients may describe amenorrhea; in less severe cases, hypomenorrhea; or recurrent pregnancy loss due to inadequate placentation (March, 2011). In their evaluation of 292 women with intrauterine adhesions, Schenker and Margalioth (1982) noted delivery of term pregnancies in only 30 percent of 165 pregnancies. The remaining pregnancies either were spontaneously aborted (40 percent) or delivered prematurely.

If intrauterine adhesions are suspected, radiologic evaluation of the uterine cavity is often performed. If information regarding tubal patency is needed, hysterosalpingography (HSG) offers information regarding both uterine cavity and fallopian tube patency. Otherwise, saline-infusion sonography (SIS) provides an excellent alternative. Intrauterine adhesions characteristically appear as irregular, angulated filling defects within the cavity (Fig. 20-6, p. 439 and Fig. 2-23, p. 41). At times, uterine polyps, leiomyomas, air bubbles, and blood clots may masquerade as adhesions. Definitive diagnosis requires hysteroscopy. To improve fertility rates or to relieve symptomatic hematometra, hysteroscopic lysis of adhesions is the preferred surgical treatment. The procedure is described in Section 44-18 (p. 1069), and fertility advantages are discussed in Chapter 21 (p. 461). Although still experimental, recent research has proposed the use of uterine or bone marrow–derived stem cells in the treatment of Asherman syndrome and other reproductive disorders (Santamaria, 2018; Simoni, 2018).

HYPERGONADOTROPIC HYPOGONADISM

The term *hypergonadotropic hypogonadism* describes any process in which: (1) ovarian function is reduced or absent (hypogonadism) and (2) the gonadotropins, LH and FSH, have elevated serum levels (hypergonadotropic) due to absent negative sex-steroid and inhibin feedback. This category of disorders implies primary dysfunction within the ovary rather than hypothalamic or pituitary dysfunction (Table 17-6). This process can also be termed *premature menopause* or *premature ovarian failure (POF)*. The term *premature ovarian insufficiency* or *primary ovarian insufficiency (POI)* is currently preferred as it conveys the fact that ovarian function may fluctuate before complete oocyte depletion. This may lead to occasional transient menses resumption or even pregnancy in 5 to 10 percent of patients (Bidet, 2011). For our purposes, the term premature ovarian insufficiency will be used.

Miscellaneous

POI is defined as loss of oocytes and the surrounding support cells prior to age 40 years. The diagnosis is determined by two serum FSH levels that measure greater than a threshold range of 30 to 40 mIU/mL and are obtained at least 1 month apart. This definition distinguishes POI from the physiologic loss of ovarian function, which occurs with normal menopause. The incidence of POI has been estimated at 1 in 1000 women younger than 30 years and at 1 in 100 women younger than 40 (Coulam, 1986).

Careful evaluation is mandatory as the diagnosis and effective treatment may have significant implications for the patient's psychologic, cardiovascular, bone, and sexual health. The finding of a genetic disorder may also require evaluation of family members. Nevertheless, in most cases, an etiology for POI is not determined (American College of Obstetricians and Gynecologists, 2018c).

Heritable Disorders

Gonadal Dysgenesis

Gonadal dysgenesis is the most frequent cause of POI. In this disorder, a normal complement of germ cells is present in the early fetal ovary. However, oocytes undergo accelerated atresia, and the ovary is replaced by a fibrous streak—termed a *streak*

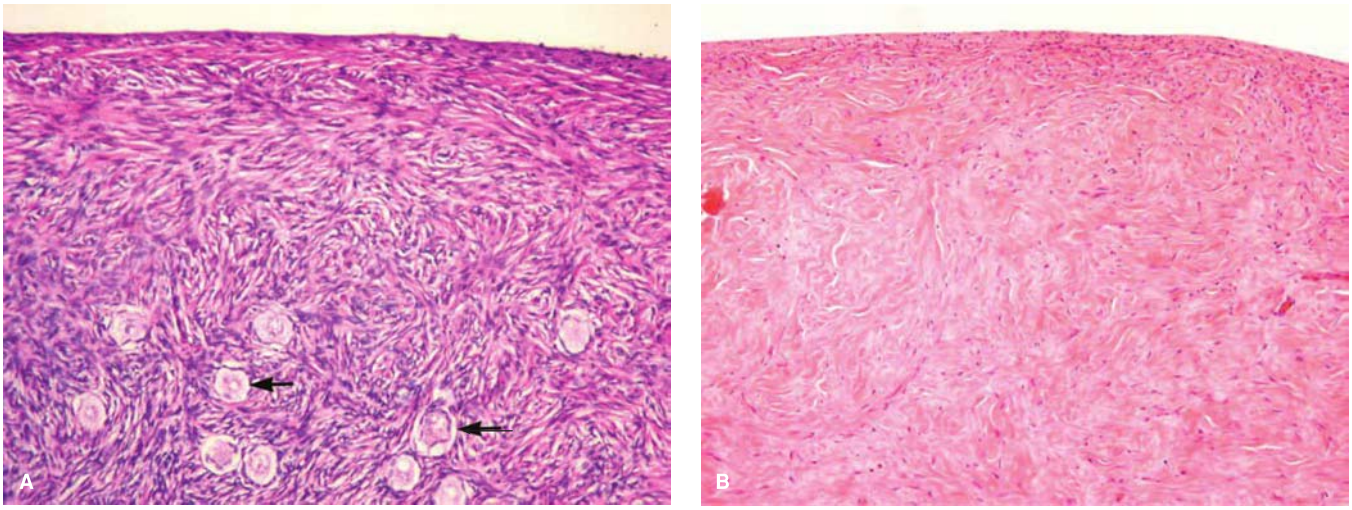

FIGURE 17-3 Photomicrographs of histologic samples. **A.** Normal premenopausal ovarian cortex with multiple primordial follicles. gonad (Figs. 17-3 and 17-4) (Singh, 1966). Individuals with gonadal dysgenesis may present with various clinical features and can be divided into two broad groups based on whether their karyotype is normal or abnormal (Rossetti, 2017). These are all discussed further in Chapter 19 (p. 412).

Those with normal karyotype (46,XX or 46,XY) are described as having "pure" gonadal dysgenesis. Patients with a 46,XY genotype and gonadal dysgenesis (Swyer syndrome) are phenotypically female due to absent testosterone and absent antimüllerian hormone (AMH) secretion by dysgenetic testes. The etiology of the gonadal failure in both genetically male and female patients is poorly understood but is likely due to single gene defects or destruction of gonadal tissue in utero, perhaps by infection or toxins (Hutson, 2014).

Those with abnormal karyotype include Turner syndrome (45,X) and chromosomal mosaics such as 45,X/46,XX or 45,X/46,XY. In general, approximately 90 percent of individuals with gonadal dysgenesis from a loss of X genetic material never menstruate. The remaining 10 percent have sufficient residual follicles to experience menses and rarely may achieve pregnancy. However, the menstrual and reproductive lives of such individuals are invariably brief (Kaneko, 1990; Tho, 1981).

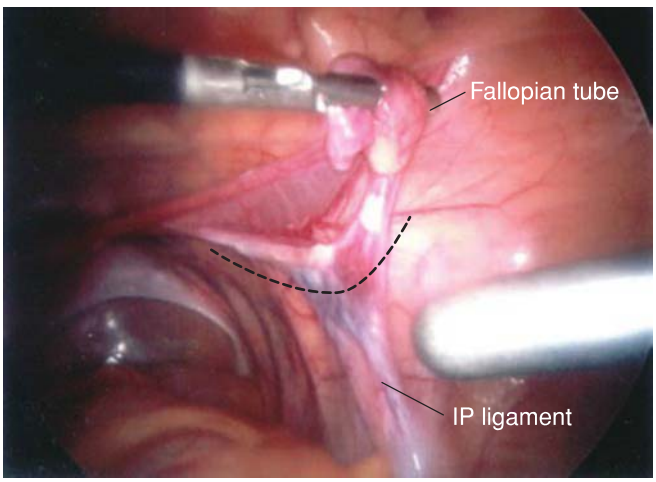

FIGURE 17-4 Photograph taken during laparoscopy of a streak gonad (*dotted line*). IP = infundibulopelvic. (Reproduced with permission from Dr. Victor Beshay.)

As noted, in some cases of gonadal dysgenesis, a Y chromosome is present. If Y chromosomal material is found, the streak gonads are removed because nearly 25 percent of these patients will develop a malignant germ cell tumor (Chap. 36, p. 756) (Cools, 2018; Pyle, 2017). Thus, chromosomal analysis is performed in all cases of amenorrhea associated with POI, particularly before age 30. The presence of a Y chromosome cannot be determined clinically, as only a few patients will demonstrate signs of androgen excess.

Specific Genetic Defects

In addition to chromosomal abnormalities, patients may experience POI due to single gene mutations (Cordts, 2011). First, a significant relationship is noted between fragile X syndrome and POI (American College of Obstetricians and Gynecologists, 2017a). This syndrome is caused by a triple repeat sequence mutation in the X-linked *FMR1* (fragile X mental retardation) gene. This gene is unstable, and its size can expand during parent-to-child transmission. The fully expanded mutation (>200 CGG repeats) becomes hypermethylated, resulting in silencing of gene expression. As such, this fully expanded mutation is the most common known inherited genetic cause of mental retardation and of autism. Males with the so-called premutation (50 to 200 CGG repeats) are at risk for fragile X–associated tremor/ataxia syndrome (FXTAS). Females with the premutation have a 13- to 26-percent risk of developing POI, although the mechanism is unclear. An estimated 0.8 to 7.5 percent of sporadic POI and 13 percent of familial POI cases are due to premutations in this gene. The prevalence of premutations in women approximates 1 in 129 to 300 (Wittenberger, 2007).

Less common gene defects are *CYP17* mutations. These decrease 17α-hydroxylase and 17,20-lyase activity and thereby

prevent production of cortisol, androgens, and estrogens (Fig. 16-5, p. 339). Affected patients have sexual infantilism and primary amenorrhea due to absent estrogen secretion. *Sexual infantilism* describes patients with a lack of breast development, absent pubic and axillary hair, and a small uterus. Mutations in *CYP17* also raise adrenocorticotropin hormone (ACTH) release, thereby stimulating mineralocorticoid secretion. This, in turn, leads to hypokalemia and hypertension (Miller, 2018).

Mutations in genes that encode LH and FSH receptors also have been reported. These defects prevent normal responses to circulating gonadotropins, a condition termed *resistant ovary syndrome* (Aittomaki, 1995; Latronico, 2013). Identification of other single-gene mutations that can cause POI is an area of active investigation. The list of implicated genes now includes those that encode both estrogen receptors (ERα and ERβ), extracellular signaling proteins (specifically, BMP15), and transcription factors FOXL2, FOX03, and SF-1 (Cordts, 2011; Goswami, 2005). These factors provide further insights into normal ovarian physiology and may lead to new infertility treatments and contraceptive options.

Perrault syndrome, which is characterized by sensorineural hearing loss and ovarian dysfunction, is gaining attention. Ovarian disturbances range from gonadal dysgenesis and primary amenorrhea to POI. Associated neurologic features include learning disabilities, developmental delay, and cerebellar ataxia (Newman, 2018).

Although frequently cited, galactosemia is a rare cause of POI. Classic galactosemia affects 1 in 30,000 to 60,000 live births. Inherited as an autosomal recessive disorder, this condition leads to abnormal galactose metabolism due to a deficiency of galactose-1-phosphate uridyl transferase, encoded by the *GALT* gene. Galactose metabolites are believed to have a direct toxic effect on many cell types, including germ cells. Potential complications include neonatal death, ataxic neurologic disease, cognitive disabilities, and cataracts (Thakur, 2018). In one large cohort study, only 68 percent of girls achieved spontaneous menarche. Of these, fewer than 15 percent were still cycling regularly after 10 years (Frederick, 2018). Treatment is lifelong dietary restriction of galactose, which is present in milk-based foods, and may not reliably prevent POI development. Galactosemia is frequently diagnosed during newborn screening programs or during pediatric evaluation of impaired growth and development. This is typically long before a patient would present to a gynecologist.

Acquired Abnormalities

Hypergonadotropic hypogonadism can be acquired from infection, environmental exposures, autoimmune disease, or medical treatments. Of these, infectious causes of POI are rare and poorly understood, and mumps oophoritis is the most frequently reported (Hviid, 2008). Various environmental toxins have a clear detrimental effect on follicular health. These include cigarette smoking, heavy metals, solvents, pesticides, and industrial chemicals (Budani, 2017; Mlynarcikova, 2005; Vabre, 2017).

Autoimmune disorders historically are said to account for an estimated 40 percent of POI cases. This may be an overestimate as the data behind this statistic are limited (Hoek, 1997). Ovarian dysfunction may be one component of the inherited autoimmune polyendocrine syndromes APS-1 and APS-2. Both syndromes are characterized by circulating autoantibodies and lymphocytic infiltration of affected tissues that lead to organ failure. With an estimated prevalence of 1:1000, APS-2 is more common and is associated with Addison's disease, thyroid disease, and type 1 diabetes mellitus (Husebye, 2018). POI is associated with systemic lupus erythematosus. Ovarian effects likely stem from treatment of severe cases with alkylating chemotherapeutics from the disease process itself (Oktem, 2016). Myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, inflammatory bowel disease, and autoimmune hemolytic anemia also have been linked to POI (Silva, 2014). Although several antiovarian antibodies have been characterized, no validated serum antibody marker is currently available to aid autoimmune POI diagnosis (American Society for Reproductive Medicine, 2008).

Iatrogenic ovarian failure is relatively common. This group includes patients who have undergone surgical removal of the ovaries or cystectomy. Alternatively, a woman may experience amenorrhea following pelvic radiation for cancer or following chemotherapy for treatment of malignancies or severe autoimmune disease.

With the last two, the chance of developing POI is correlated with increasing radiation and chemotherapeutic dose. Patient age also is a significant factor, and younger patients are less likely to develop failure and more likely to regain ovarian function over time (Gradishar, 1989). With radiotherapy, ovaries are preventively repositioned using surgery (oophoropexy), if possible, out of the anticipated radiation field prior to therapy (Terenziani, 2009). Of chemotherapeutic drugs, alkylating agents are believed to be particularly damaging to ovarian function. Preventive adjuvant GnRH analogues may lower rates of chemotherapy-induced POI (Chap. 27, p. 594). Although this approach remains controversial, recent studies and meta-analyses show promising results (Chen, 2011; Lambertini, 2018). Importantly, recent advances in oocyte and ovarian tissue cryopreservation and in vitro maturation make it likely that oocyte harvest prior to treatment will become the preferred approach when feasible.

HYPOGONADOTROPIC HYPOGONADISM

The term *hypogonadotropic hypogonadism* implies that the primary abnormality lies in the hypothalamic-pituitary axis. As a result, poor gonadotropin stimulation of the ovaries leads to impaired follicular development. Generally in these patients, LH and FSH levels, although low, will still be in the detectable range (<5 mIU/mL). However, levels may be undetectable in patients with complete absence of hypothalamic stimulation, such as occurs in forms of inherited hypothalamic abnormalities. In addition, absent pituitary function due to abnormal development or severe pituitary damage may lead to similarly low levels. Thus, the group of hypogonadotropic hypogonadism disorders may be viewed as a continuum with perturbations leading to luteal dysfunction, oligomenorrhea, and, in the most severe presentation, amenorrhea.

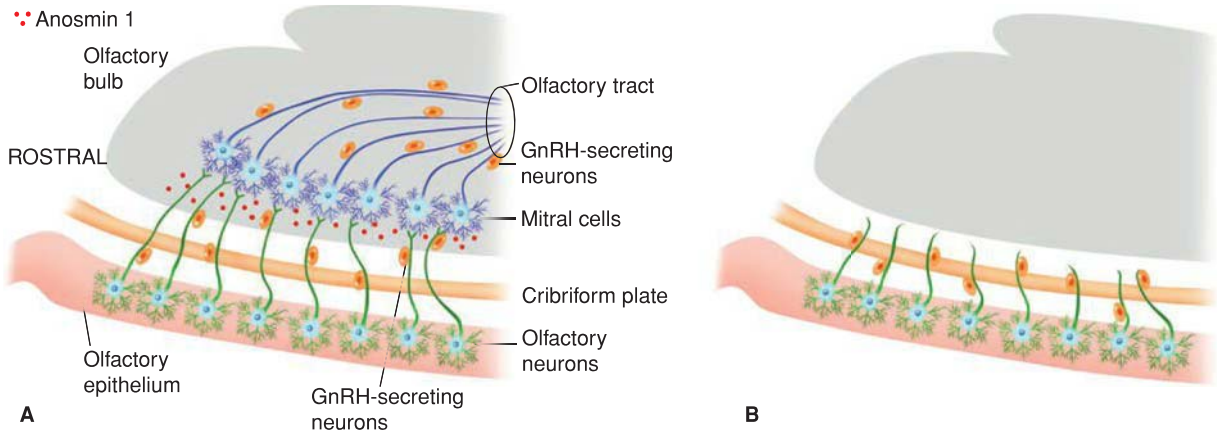

FIGURE 17-5 Normal GnRH neuron migration and the pathogenesis of Kallmann syndrome. **A.** During normal development, olfactory neurons arising in the olfactory epithelium extend their axons through the cribriform plate of the ethmoid bone to reach the olfactory bulb. Here, these axons synapse with dendrites of mitral cells, whose axons form the olfactory tract. Mitral cells secrete anosmin-1, which is the protein product of the *KAL1* gene. This protein is necessary to direct the olfactory axons to their correct location in the olfactory bulb. The GnRH-secreting neurons use this axonal path to migrate from the olfactory placode to the hypothalamus. **B.** Patients with Kallmann syndrome due to a *KAL1* mutation lack anosmin-1 expression. As a result, the axons of the olfactory neurons cannot interact properly with mitral cells, and their migration ends between the cribriform plate and olfactory bulb. As GnRH neuronal migration is dependent on this axonal trail, the GnRH secretion pathway likewise ends at this location.

Hypothalamic Disorders

Inherited Hypothalamic Abnormalities

Inherited hypothalamic abnormalities primarily consist of those patients with idiopathic hypogonadotropic hypogonadism (IHH). A subset has associated defects in the ability to smell (hyposmia or anosmia) and are said to have Kallmann syndrome. This syndrome can be inherited as an X-linked, autosomal dominant, or autosomal recessive disorder (Cadman, 2007). The X-linked form was the first to be characterized and follows mutation in the *KAL1* gene on the short arm of the X chromosome. Expressed during fetal development, this gene encodes an adhesion protein named anosmin-1. As this protein is critical for normal migration of both GnRH and olfactory neurons, loss of normal anosmin-1 expression results in both reproductive and olfactory deficits (Fig. 17-5) (Franco, 1991). Kallmann patients have a normal complement of GnRH neurons, however, these neurons fail to migrate and instead remain near the nasal epithelium (Quinton, 1997). As a result, locally secreted GnRH is unable to stimulate gonadotropes in the anterior pituitary gland to release LH and FSH. In turn, marked declines in ovarian estrogen production result in absence of breast development and menstrual cycles.

Kallmann syndrome is also associated with midline facial anomalies such as cleft palate, unilateral renal agenesis, cerebellar ataxia, epilepsy, neurosensory hearing loss, and synkinesis (mirror movements of the hands). Kallmann syndrome can be distinguished from IHH by olfactory testing. This is performed easily in the office with strong odorants such as ground coffee or perfume. Interestingly, many of these patients are unaware of their olfactory deficit.

During the past 15 years, an array of autosomal genes has been identified that contribute to normal development, migration, and secretion by GnRH neurons (Caronia, 2011; Howard, 2018; Layman, 2013). Mutations in several of these genes have been described in patients with hypothalamic amenorrhea. Genes include *FGF8*, *KAL1*, *NELF*, *PROK2*, *PROKR2*, *CHD7*, *KISS1/KISS1R*, and *LEP/LEPR*. As a result, the percentage of patients in whom this disorder need be considered idiopathic is gradually decreasing. Of note, mutation in the *CHD7* gene may cause either normosmic IHH or Kallmann syndrome, thereby blurring the distinction between these disorders.

Acquired Hypothalamic Dysfunction

Acquired hypothalamic abnormalities are much more frequent than inherited deficiencies. Most commonly, gonadotropin deficiency leading to chronic anovulation is believed to arise from functional disorders of the hypothalamus or higher brain centers. Also called "hypothalamic amenorrhea," this diagnosis encompasses three main categories: eating disorders, excessive exercise, and stress. From a teleologic perspective, amenorrhea in time of starvation or extreme stress can be seen as a mechanism to prevent pregnancy at a time in which resources are suboptimal for raising a child. Each woman appears to have her own hypothalamic "setpoint" or sensitivity to environmental factors. For example, individual women can tolerate markedly different amounts of stress without developing amenorrhea. In addition to amenorrhea, these conditions are associated with infertility and cardiovascular, bone, and psychologic effects (Gordon, 2017; Shufelt, 2017).

Eating Disorders. Anorexia nervosa and bulimia, both described in Chapter 14 (p. 305), can lead to amenorrhea (American College of Obstetricians and Gynecologists, 2018a). Hypothalamic dysfunction is severe in anorexia and may affect other hypothalamic-pituitary axes in addition to the reproductive axis. Amenorrhea in anorexia nervosa can precede, follow, or appear coincidentally with weight loss. In addition, even with return to normal weight, not all women with anorexia will regain normal menstrual function. Patients with premenarchal

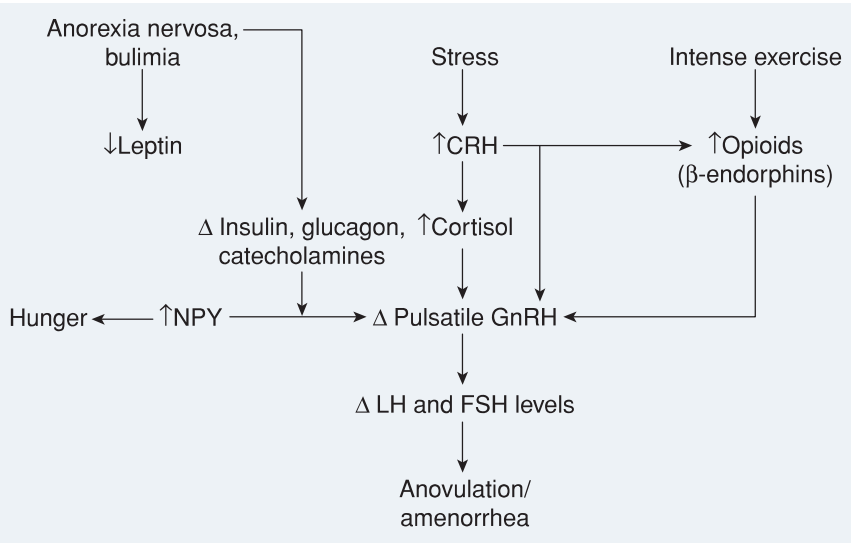

FIGURE 17-6 Diagram depicting a simplified model for the development of amenorrhea in women with eating disorders, high stress levels, or rigorous exercise. CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; NPY = neuropeptide Y.

onset of anorexia are at particular risk for protracted amenorrhea (Dempfle, 2013).

Exercise-induced Amenorrhea. This is most common in women whose exercise regimen is associated with significant loss of fat, including ballet, gymnastics, and long-distance running. In those women who continue to menstruate, cycles are notable for their variability in cycle interval and length due to reduced ovulatory function (De Souza, 1998). Puberty may be delayed in girls who begin training before menarche (Frisch, 1981).

An appreciation for the link between exercise and reproductive health has led to the concept of the *female athlete triad,* which consists of menstrual dysfunction, low energy availability with or without disordered eating, and low bone mineral density in extreme athletes (American College of Obstetricians and Gynecologists, 2017b). Two international symposia held in this field have begun to develop risk stratification and recommendations for this population (Ackerman, 2018; Joy, 2014).

In 1970, Frisch and Revelle proposed that an adolescent girl needed to achieve a critical body weight to begin menstruating (Frisch, 1970). This mass was initially postulated to approximate 48 kilograms and was subsequently refined to a minimal body mass index (BMI) approaching normal, which is ≥19. Subsequent studies suggest that, although body fat and reproductive function show clear correlation at both ends of the weight spectrum, overall energy balance better predicts the onset and maintenance of menstrual cycles (Billewicz, 1976; Gonzales, 1996; Kaplowitz, 2008). For example, many elite athletes regain menstrual cyclicity following a decrease in exercise intensity prior to any gain in weight (Abraham, 1982). Of note, no weight or BMI has been determined to reliably predict pubertal onset.

Stress-induced Amenorrhea. This may be associated with clearly traumatic life events. Nevertheless, less severe life events and even positive events may be associated with stress. For example, stress-related amenorrhea is frequently associated with leaving for college, test taking, or wedding planning.

Pathophysiology of Functional Hypothalamic Amenorrhea. Eating disorders, exercise, and stress may disturb menstrual function through overlapping mechanisms. This observation may be in part because these problems are often concurrent. For example, women with eating disorders frequently exercise excessively and are undoubtedly under stress as they attempt to control their eating patterns. Figure 17-6 depicts a simplified model for the development of amenorrhea in these patients. Importantly, each cause of functional hypothalamic amenorrhea may act via one or all of these pathways. Furthermore, in many cases, the factors known to affect reproductive function are likely acting indirectly on GnRH neurons through various neuronal subtypes that have synaptic connections to GnRH neurons. The kisspeptin neuronal system is likely a critical mediator between physiologic status and GnRH secretion and is discussed in Chapter 16 (Wahab, 2018).

Exercise is associated with an increase in endogenous opioid (β-endorphin) levels, producing the so-called runner's high. Opioids alter GnRH pulsatility. Opioids further alter reproduction through effects on ovarian, endometrial, and myometrial function (Böttcher, 2017).

As part of the stress response, each of these conditions may lead to greater corticotropin-releasing hormone (CRH) release by the hypothalamus, which in turn results in cortisol secretion by the adrenal gland. CRH alters the pattern of pulsatile GnRH secretion, whereas cortisol may act directly or indirectly to disrupt GnRH neuronal function.

Eating disorders are thought to disturb ovulatory function through several hormonal factors including insulin, insulin-like growth factor 1, cortisol, adiponectin, ghrelin, and leptin (Misra, 2014). First identified in 1994, leptin is a 167-amino-acid protein encoded by the *ob* gene and produced in white adipose tissue (Zhang, 1994). Leptin receptors have been identified in the central nervous system (CNS) and a wide range of peripheral tissues. Primarily produced in adipose tissue, leptin provides an important link between energy balance and reproduction, although it is one of many mechanisms (Chou, 2014; Schneider, 2004). Leptin has been termed a "satiety factor" as human leptin gene mutation results in morbid obesity, diabetes mellitus, and hypogonadism. This trio of abnormalities can be successfully reversed with recombinant human leptin treatment (Licinio, 2004).

Patients with anorexia nervosa have been found to have low circulating leptin levels (Mantzoros, 1997). It is hypothesized that a decrease in leptin production due to weight loss could secondarily stimulate neuropeptide Y, which is known to stimulate hunger and alter GnRH pulsatility. Leptin likely acts through various additional neurotransmitters and neuropeptides

that include the β-endorphins and α-melanocyte-stimulating hormone.

Pseudocyesis. Although rare, this is considered in any woman with amenorrhea and pregnancy symptoms but negative pregnancy test results. Pseudocyesis exemplifies the ability of the mind to control physiologic processes. More than 500 cases of pseudocyesis are reported in the medical literature in women ranging from ages 6 to 79 years. These patients fervently believe that they are pregnant and subsequently demonstrate several pregnancy signs and symptoms, including amenorrhea.

Endocrine evaluation in a limited number of patients has suggested a pattern of hormonal derangements. These include alterations in LH pulse frequency concurrent with elevated serum androgen levels, which may explain the observed amenorrhea. Elevated serum prolactin levels and resultant galactorrhea have been noted in a subset of patients. Nocturnal growth hormone secretion also appears blunted (Tarin, 2013).

A common link in these patients is a history of severe grief, such as recent miscarriage, infant death, or longstanding infertility. Pseudocyesis may be more common in developing countries, where societal pressure to produce children may be strong (Seeman, 2014). Psychiatric treatment is generally required to treat the associated depression, which is often exacerbated when the patient is informed that she is not pregnant (Whelan, 1990).

Anatomic Destruction. Any process that destroys the hypothalamus can impair GnRH secretion and lead to hypogonadotropic hypogonadism and amenorrhea. Due to the complex neurohormonal input to the GnRH neurons, abnormalities do not need to directly interact with GnRH neurons but may operate indirectly by altering the activity of modulatory neurons.

The tumors most often associated with amenorrhea include craniopharyngiomas, germinomas, endodermal sinus tumors, eosinophilic granuloma (Hand-Schüller-Christian syndrome), gliomas, and metastatic lesions. The most common of these tumors, craniopharyngiomas, are located in the suprasellar region and frequently present with headaches and visual changes. Alternatively, impaired GnRH secretion may follow trauma, radiation, infections such as tuberculosis, or infiltrative diseases such as sarcoidosis.

Anterior Pituitary Gland Disorders

The anterior pituitary gland consists of gonadotropes (producing LH and FSH), lactotropes (prolactin), thyrotropes (thyroid-stimulating hormone), corticotropes (adrenocorticotropic hormone), and somatotropes (growth hormone) (Chap. 16, p. 346). Although various disorders may directly affect gonadotropes, many causes of pituitary-derived amenorrhea may also follow abnormalities in other pituitary cell types, which in turn alter gonadotrope function.

Inherited Abnormalities

Our understanding of genetic mechanisms that regulate normal pituitary development and function is rapidly advancing. First, patients with pituitary hormone deficiency combined with central facial and/or neurologic defects due to a failed midline fusion have been described. This syndrome is known as *septo-optic dysplasia*. Many of these patients carry mutations in the *PROP1* gene (Cadman, 2007). Second, mutations in genes that encode the LH or FSH β-subunits or the GnRH receptor have also been identified as rare causes of hypogonadotropic hypogonadism. Last, mutations in genes encoding the nuclear hormone receptors SF-1 and DAX1 (NR0B1) as well as genes encoding the G protein–coupled receptor 54 (GPR54) for kisspeptin 1 are associated with hypothalamic and pituitary dysfunction (Matthews, 1993; Pallais, 2006; Seminara, 2006; Weiss, 1992).

Acquired Pituitary Dysfunction

Most pituitary dysfunction is acquired after menarche and therefore presents with normal pubertal development followed by secondary amenorrhea. Nevertheless, in rare cases, these disorders may begin prior to puberty, resulting in delayed puberty and primary amenorrhea (Howlett, 1989).

Pituitary adenomas are the most frequent cause of acquired pituitary dysfunction (Chap. 16, p. 361) (Molitch, 2017). These most commonly secrete prolactin, but excessive secretion of any pituitary-derived hormone can result in amenorrhea. Significantly elevated serum prolactin levels (>100 ng/mL) are almost always due to a pituitary mass.

Increased serum prolactin levels are found in as many as one-tenth of amenorrheic women, and more than half of women with both galactorrhea and amenorrhea have elevated prolactin levels (the "galactorrhea-amenorrhea syndrome"). Mechanistically, dopamine is released by the hypothalamus and acts on the anterior pituitary. Dopamine is the primary regulator of prolactin biosynthesis and secretion and plays an inhibitory role. Thus, elevated prolactin levels feed back to the hypothalamus and are associated with a reflex rise in central dopamine production to lower prolactin concentrations. This rise in central dopamine levels alters GnRH neuronal function.

Pituitary tumors also may indirectly alter gonadotrope function by a mass effect. First, tumor growth may compress neighboring gonadotropes. Second, damage to the pituitary stalk can disrupt dopamine's pathway to inhibit prolactin secretion. In this latter case, resulting elevated prolactin levels lead to elevated central dopamine levels that presumably interfere with menstrual function through the same mechanisms described in the previous paragraph.

As in the hypothalamus, pituitary function may also be diminished by inflammation, infiltrative disease, metastatic lesions, surgery, or radiation treatment (Dahan, 2017). Although a rare condition, peripartum lymphocytic hypophysitis can be a dangerous cause of pituitary failure. Infiltrative diseases include sarcoidosis and hemochromatosis.

Sheehan syndrome refers to panhypopituitarism. It classically follows massive postpartum hemorrhage and associated hypotension. The abrupt, severe hypotension leads to pituitary ischemia and necrosis (Kelestimur, 2003). Patients with the most severe form develop shock due to pituitary apoplexy. Pituitary apoplexy is characterized by a sudden onset of headache, nausea, visual deficits, and hormonal dysfunction due to acute hemorrhage or infarction within the pituitary. In less severe forms, loss of gonadotrope activity in the pituitary leads to anovulation and subsequent amenorrhea. Damage to the other specific pituitary cell types lead to a failure to lactate, loss of

sexual and axillary hair, and hypothyroidism or adrenal insufficiency symptoms. Pituitary cell types are differentially sensitive to damage. For this reason, prolactin secretion deficiency is the most common, followed by loss of gonadotropin and growth hormone release, loss of ACTH production, and, least commonly, decreases in thyroid-stimulating hormone (TSH) secretion (Veldhuis, 1980).

Other Causes of Hypogonadotropic Hypogonadism

Hypogonadotropic amenorrhea may be observed in various chronic diseases including end-stage kidney disease, liver disease, malignancies, acquired immunodeficiency syndrome, and malabsorption syndromes. The mechanisms by which these disorders result in menstrual dysfunction are poorly understood. End-stage kidney disease is associated with increased serum prolactin and altered leptin levels, both of which may disrupt normal GnRH pulsatility (Ghazizadeh, 2007). Of patients with nonalcoholic chronic liver disease, the cause of the low gonadotropin levels is unknown and is observed only in a subset of those with amenorrhea (Cundy, 1991). Chronic diseases may produce amenorrhea through common mechanisms, such as stress and nutritional deficiencies. For example, patients with malabsorption due to celiac disease may have delayed menarche, secondary amenorrhea, and early menopause, which have been attributed to deficiencies in trace elements such as zinc and selenium. These are required for normal gonadotropin biosynthesis and secretion (Walker, 2019).

EUGONADOTROPIC AMENORRHEA

Several disorders that produce amenorrhea are not associated with significantly abnormal gonadotropin levels, at least as measured at a single point in time, as is done in clinical settings. Even so, gonadotropin amplitude or pulse frequency is likely disturbed in these patients. As a result, chronic sustained sex-steroid secretion interferes with the normal feedback between the ovary and the hypothalamic-pituitary axis. Normal oocyte maturation and ovulation are impaired, and menstruation fails to occur.

Due to relatively normal gonadotropin levels, these patients will secrete estrogen and therefore can also be said to have *chronic anovulation with estrogen present*. This is in contrast to patients with ovarian failure or hypothalamic-pituitary failure, in whom estrogen levels are low or absent. This distinction may be useful during evaluation and treatment.

Polycystic Ovarian Syndrome

This syndrome is by far the most common cause of chronic anovulation with estrogen present and is discussed fully in Chapter 18 (p. 389). Patients with PCOS may have various menstrual presentations. First, complete amenorrhea may follow anovulation. Without ovulation, progesterone is lacking, and an absent progesterone withdrawal fails to prompt menses. In some women with PCOS, however, amenorrhea may be attributable to the ability of androgens, which are elevated in PCOS patients, to atrophy the endometrium. Alternatively, heavy menstrual or intermenstrual bleeding can result from unopposed estrogen stimulation of the endometrium. Within this unstable, thickened proliferative-phase endometrium, episodic stromal breakdown and shedding leads to irregular bleeding. Vessels may be abnormally dilated in anovulatory endometria, and bleeding may be severe. Last, women with PCOS may experience occasional ovulatory cycles, and normal withdrawal menses or pregnancy can occur.

Nonclassic Congenital Adrenal Hyperplasia

This condition closely mimics the presentation of PCOS with hyperandrogenism and irregular menstrual cycles. Most commonly, nonclassic congenital adrenal hyperplasia (CAH), also termed *adult-onset CAH* or *late-onset CAH*, is due to a mutation in the *CYP21A2* gene, which encodes the 21-hydroxylase enzyme. With a mild mutation, patients are asymptomatic until adrenarche, a time that requires greater adrenal steroidogenesis. Patients with CAH are unable to convert an adequate percentage of progesterone to cortisol and aldosterone, thus raising the production of androgens (Fig. 16-5, p. 339). As in PCOS, elevated androgen levels blunt oocyte maturation and thereby result in anovulation and amenorrhea.

Ovarian Tumor

Although uncommon, chronic anovulation with estrogen present can also be observed with ovarian tumors producing either estrogens or androgens. As discussed in Chapter 36, examples include granulosa cell tumors, theca cell tumors, and other sex cord–stromal tumors (p. 763) (Pectasides, 2008; Thomas, 2012).

Hyperprolactinemia and Hypothyroidism

Although hyperprolactinemia can cause hypogonadotropic hypogonadism, as described earlier, many hyperprolactinemic women may instead have relatively normal gonadotropin levels (p. 380). As a group, however, their estrogen levels will be mildly depressed. Aside from pituitary adenomas, other circumstances can significantly raise prolactin levels. First, many medications and herbs are associated with hyperprolactinemia, galactorrhea, and disrupted menstrual cycling (Table 13-2, p. 285). The antipsychotic group of medications is a frequent cause.

Second, primary hypothyroidism is the most common reason for elevated prolactin levels. One example is Hashimoto thyroiditis. In this disorder, the decline in circulating thyroid hormone levels results in a compensatory rise in hypothalamic thyrotropin-releasing hormone (TRH) secretion. TRH prompts pituitary gland thyrotropes to produce TSH. In addition, TRH also binds to pituitary lactotropes, increasing prolactin secretion. This tight link between thyroid function and prolactin levels justifies measurement of TSH and prolactin levels during evaluation of galactorrhea or amenorrhea.

Whether due to adenoma, medications, or hypothyroidism, prolactin elevation creates a compensatory rise in central levels of dopamine, the primary inhibitor of prolactin secretion. Greater central dopamine levels alter GnRH secretion, thereby disrupting normal cyclic gonadotropin secretion and preventing

ovulation. With thyroid disease, additional proposed mechanisms include direct effects of thyroid hormone and prolactin on peripheral cells, as thyroid receptors are found in most cell types. Prolactin receptors have been identified in the ovary and in the endometrium. Moreover, thyroid hormone raises sex hormone–binding globulin levels, which alters the levels of unbound, and thereby active, ovarian steroids.

These potentially discordant effects are reflected in the various bleeding patterns seen with thyroid disease (Krassas, 2010). Classically, hypothyroidism is stated to cause anovulation and subsequent heavy menstrual bleeding (Chap. 8, p. 192). Hyperthyroidism is implicated in amenorrhea. Nevertheless, these patterns are not strictly observed. As might be expected, the likelihood of menstrual abnormality correlates with the severity of the thyroid function disturbance (Kakuno, 2010).

EVALUATION

History

Figure 17-7 offers an algorithm for approaching the patient with amenorrhea. Initial questions investigate whether pubertal

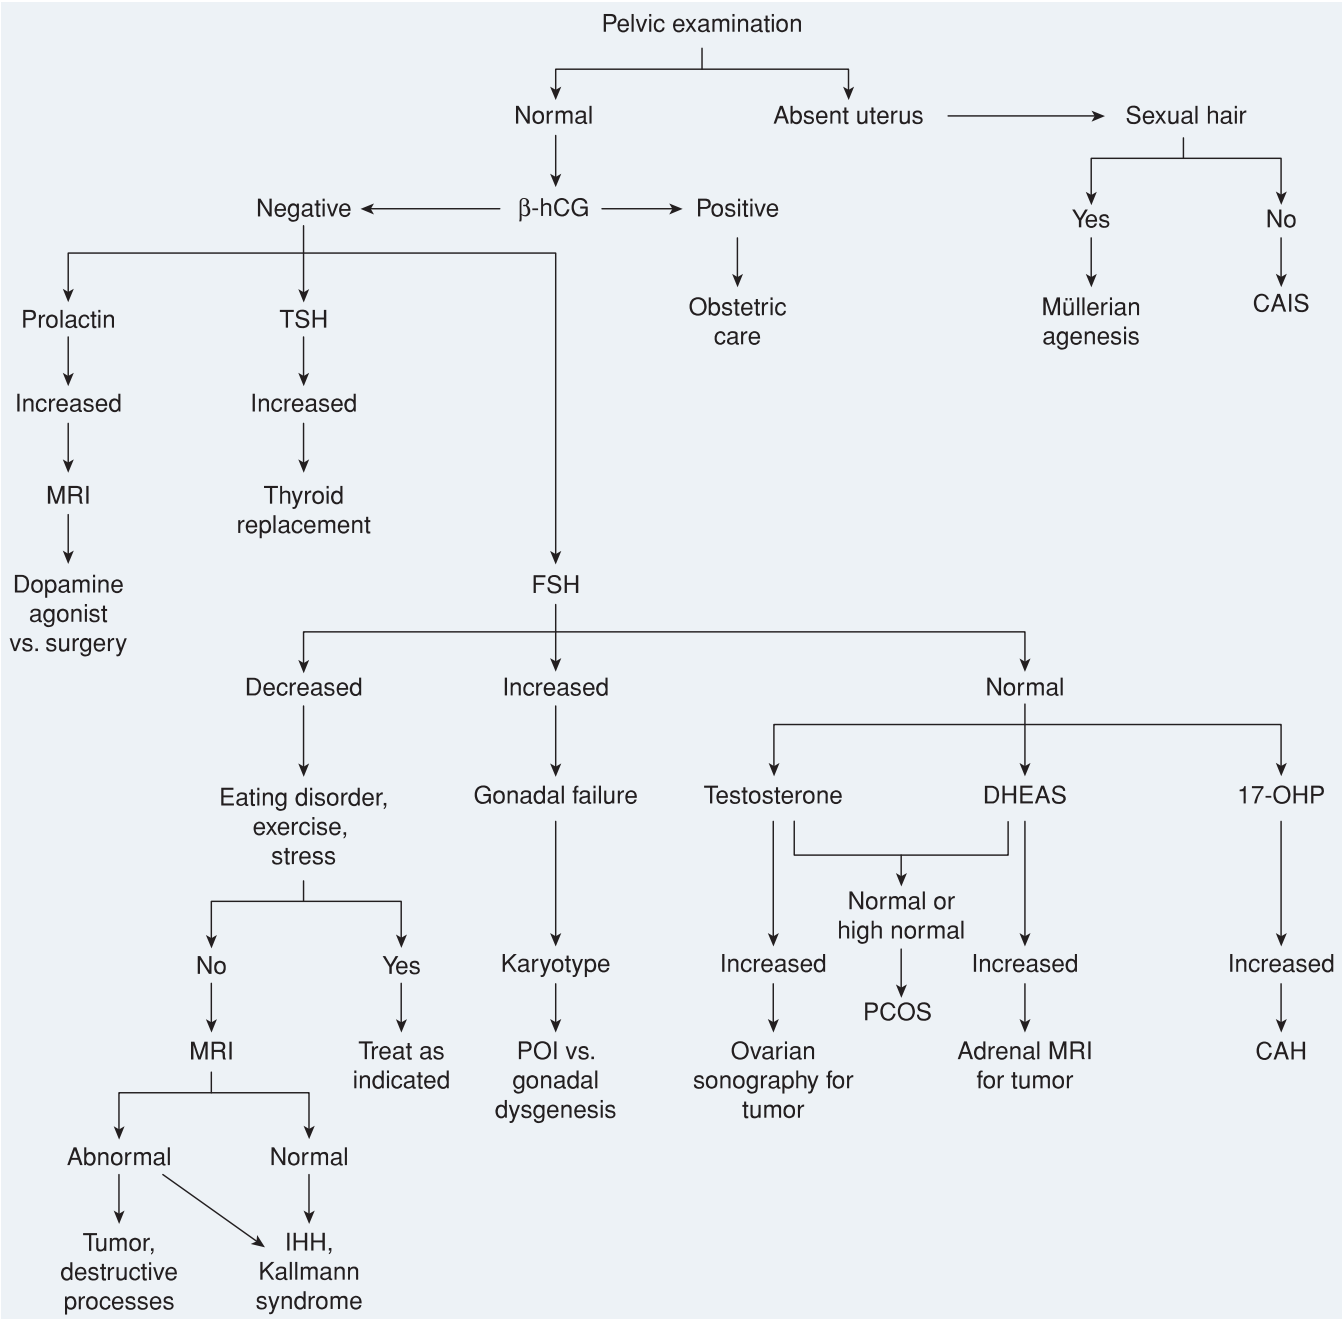

FIGURE 17-7 Diagnostic algorithm to evaluate amenorrhea. CAH = congenital adrenal hyperplasia; CAIS = complete androgen insensitivity syndrome; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; IHH = idiopathic hypogonadotropic hypogonadism; MRI = magnetic resonance imaging; 17-OHP = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POI = premature ovarian insufficiency; TSH = thyroid-stimulating hormone.

Tanner stages have been reached and whether menses have begun (Fig. 15-3, p. 322). The cycle interval, duration, and amount of menstrual flow are characterized. Also, the development of amenorrhea may be temporally correlated with androgen excess, eating disorders, stress, intensive exercise, cancer therapy, or other illnesses. Surgical history focuses on prior pelvic surgery, especially intrauterine surgery. Patients are questioned regarding postoperative infection or other surgical complications.

A review of symptoms can be helpful. For example, new-onset headaches or visual changes may suggest a tumor of the CNS or pituitary gland. Pituitary tumors may impinge on the optic chiasm, resulting in bitemporal hemianopsia, that is, the loss of both right and left outer visual fields. Bilateral milky breast discharge may reflect hyperprolactinemia. Thyroid disease can be associated with heat or cold intolerance, weight changes, and sleep or bowel motility abnormalities. Hirsutism and acne are often seen with PCOS or with nonclassic CAH. Cyclic pelvic pain would suggest a reproductive tract outlet obstruction. Hot flashes and vaginal dryness point to hypergonadotropic hypogonadism, that is, POI. Of note, the range, severity, and persistence of symptoms observed in women with POI appear to exceed those experienced by women with age-appropriate menopause (Allshouse, 2015).

Important questions regarding family history include premature cessation of menses or a history of autoimmune disease, including thyroid disease, which would suggest a greater risk for POI. Sudden neonatal death may have occurred in family members carrying mutations in the *CYP21A2* gene responsible for CAH.

Any medications are inventoried, especially those such as antipsychotics that raise prolactin levels. The social history investigates exposure to environmental toxins, including cigarettes.

Physical Examination

General appearance can be helpful in the evaluation of amenorrhea. A low BMI, perhaps in conjunction with tooth enamel erosion from recurrent vomiting, is highly suggestive of an eating disorder. Signs of Turner syndrome are evaluated, including short stature, webbed neck, shield-shaped chest, and others listed in Table 19-3 (p. 413) (Turner, 1972). Midline facial defects, such as cleft palate, are consistent with a developmental defect of the anterior pituitary gland. Hypertension in a prepubertal girl may reflect mutation in the *CYP17* gene and shunting of the steroidogenic pathway toward aldosterone.

Visual field defects, particularly bitemporal hemianopsia, may indicate a pituitary gland or CNS tumor. Skin is inspected for acanthosis nigricans, hirsutism, or acne, which may indicate PCOS or other hyperandrogenism causes. Supraclavicular fat, abdominal striae, and hypertension may be noted in those with Cushing syndrome. Hypothyroidism can present with an abnormally enlarged thyroid gland, delayed reflexes, and bradycardia. During breast examination, bilateral galactorrhea implies hyperprolactinemia.

Examination of the genitalia starts by noting hair pattern. Sparse or absent axillary or pubic hair may reflect either lack of adrenarche or androgen insensitivity syndrome. Conversely, elevated androgen levels will result in a male pattern of genital hair growth. Markedly elevated levels of androgens can produce signs of virilization, most noticeably clitoromegaly (Chap. 18, p. 397). These women may also note voice deepening and male pattern balding.

Evidence of estrogen production includes a pink, moist vagina and cervical mucus. With estrogen present, vaginal smears demonstrate mostly superficial epithelial cells, whereas with atrophy, parabasal cell numbers increase (Fig. 22-12, p. 497). Low estrogen levels also manifest with a pale or red, thin, unrugated vagina.

Determination of müllerian anomalies by physical examination is described in Chapter 19 (p. 421). Rectal and digital vaginal examination may help identify a uterus above an obstruction at the level of the introitus or in the vagina. Hematocolpos suggests normal ovarian and endometrial function.

Testing

The differential diagnosis of amenorrhea is extensive, but evaluation of most women is relatively straightforward. For all disorders, testing may be modified by patient history and physical examination. All reproductive-aged women with amenorrhea and a uterus are assumed pregnant until proven otherwise. Thus, a urinary or serum β-hCG level is almost always obtained.

Progesterone Withdrawal

Classically, patients are given exogenous progesterone and monitored for a progesterone withdrawal bleed, which follows a few days after progesterone completion (progesterone challenge test). One regimen is medroxyprogesterone acetate (Provera) given as a 10-mg daily oral dose for 10 days. If bleeding ensues after cessation, a woman is assumed to produce estrogen and to have a developed endometrium and patent outflow tract. If bleeding does not follow, then a patient is given estrogen followed by progesterone treatment. A single pack of combination oral contraceptives (COCs) works nicely for this. If a woman again fails to bleed several days after completing the 21 hormone-containing pills, an anatomic abnormality is diagnosed.

Several factors can lead to an incorrect test interpretation. First, women with high androgen levels, such as occurs with PCOS and CAH, may have an atrophic endometrium and may fail to bleed. Specifically, up to 20 percent of women in whom estrogen is present will fail to bleed following progesterone withdrawal (Rarick, 1990). Second, estrogen levels may fluctuate both in hypothalamic amenorrhea and in the early stages of ovarian failure. As a result, patients with these disorders may have at least some bleeding after progesterone withdrawal. Namely, menses may be observed after progesterone administration in up to 40 percent of women with hypothalamic amenorrhea due to stress, weight loss, or exercise and in up to 50 percent of women with POI (Nakamura, 1996). This bleeding derives from endometrium that grew prior to amenorrhea onset. Due to the limitations in interpreting the results, use of this test likely is best restricted to those situations in which accurate serum hormone measurements are unavailable.

TABLE 17-7. Tests Commonly Used in the Evaluation of Amenorrhea

Primary Laboratory Tests	Diagnosis
β-hCG	Pregnancy
FSH	Hypogonadotropic versus hypergonadotropic hypogonadism[a]
Estradiol	Hypogonadotropic versus hypergonadotropic hypogonadism
Prolactin	Hyperprolactinemia
TSH ± fT4	Thyroid disease
Secondary Laboratory Tests	
Testosterone	PCOS and exclude ovarian tumor
DHEAS	Exclude adrenal tumor
17-OHP	Nonclassic CAH
2-hour glucose tolerance test	PCOS
Fasting lipid panel	PCOS
Autoimmune testing	POI
Adrenal antibodies (*CYP21A2*)	POI
Fragile X (*FMR1* premutation)	POI
Karyotype	POI <35 years
Radiologic Evaluation	
Sonography	PCOS, uterine agenesis, or ovarian tumor
HSG or SIS	Müllerian anomaly or intrauterine synechiae
MR imaging	Müllerian anomaly or hypothalamic-pituitary disease

[a]Hypogonadotropic hypogonadism includes functional causes of hypothalamic amenorrhea (excessive exercise, eating disorders, and stress). Hypergonadotropic hypogonadism refers primarily to premature ovarian insufficiency (POI).
CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; fT4 = free thyroxine; hCG = human chorionic gonadotropin; HSG = hysterosalpingography; MR = magnetic resonance; 17-OHP = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; SIS = saline-infusion sonography; TSH = thyroid-stimulating hormone.

Serum Hormone Levels

As suggested by the American Society for Reproductive Medicine (2008), it may be more reasonable to begin with hormonal evaluation in any woman found to have a normal pelvic examination (Table 17-7). First, *serum FSH levels* are typically assessed, and levels that are low suggest hypothalamic-pituitary dysfunction. An elevated FSH level is consistent with POI. FSH levels in the normal range suggest an anatomic defect or eugonadotropic hypogonadism, such as occurs in PCOS, hyperprolactinemia, or thyroid disease. Although many patients with PCOS have elevated LH to FSH level ratios >2, testing for this relationship is unnecessary as a normal ratio does not exclude this diagnosis.

If an FSH value is low, repeating this measurement and adding an LH level, which will also be low, can help confirm hypogonadotropic hypogonadism. Additional testing may include a GnRH stimulation test. Several different protocols have been employed, but one common approach provides 100 μg of GnRH as an intravenous bolus and then measures LH and FSH levels at 0, 15, 30, 45, and 60 minutes. In patients with hypogonadotropic hypogonadism or delayed puberty, although both LH and FSH levels will be blunted, FSH levels will be high relative to LH ratios during the test (Job, 1977). Although this test is informative, providers may be unable to perform it due to a lack of consistently available clinical-grade GnRH.

In contrast, an elevated FSH level strongly suggests the presence of hypergonadotropic hypogonadism, namely, POI. This diagnosis requires two FSH levels greater than a threshold range of 30 to 40 mIU/mL and obtained at least 1 month apart. At least two elevated values are required because the course of POI may fluctuate over time. This variation likely explains the occasional pregnancy that has been reported in affected women. Patients keep a menstrual calendar while testing is completed because bleeding 2 weeks following an elevated serum FSH level may simply indicate that the sample was obtained during a normal midcycle gonadotropin surge.

As adjuncts to FSH testing, ancillary markers that will increase the sensitivity and specificity of ovarian reserve testing have been investigated. Many clinicians obtain measurements for estradiol in addition to FSH, although this has not been consistently shown to increase diagnostic accuracy. Likewise, the use of circulating serum AMH levels is an attractive option but has not been shown to be helpful (Chap. 20, p. 437) (Visser, 2012).

Prolactin and *thyroid-stimulating hormone levels* are tested in most patients with amenorrhea as prolactin-secreting adenomas and thyroid disease are relatively common and require specific treatment. Because of the relationship between hypothyroidism and prolactin levels, both hormones are measured simultaneously. If present, treatment for hypothyroidism will also normalize prolactin levels. If a TSH level is elevated, an unbound thyroxine (T_4) level is drawn to confirm clinical hypothyroidism.

Serum testosterone levels are measured in women with suspected PCOS or with clinical signs of androgen excess. Hormonal evaluation includes measurement of serum total testosterone levels. Measurement of free testosterone levels is generally unwarranted as these assays are more expensive and less reliable unless sent to a specialized laboratory. Mild elevations in testosterone levels are consistent with the diagnosis of PCOS. However, values >200 ng/dL may suggest an ovarian tumor and warrant pelvic sonography.

Serum dehydroepiandrosterone sulfate (DHEAS) production is essentially limited to the adrenal gland. Levels in high-normal range or mildly above are consistent with PCOS. Adrenal adenomas may produce circulating DHEAS levels above 700 μg/dL and merit investigation with magnetic resonance (MR) imaging or computed tomography (CT) scanning of the adrenals. Measurement of 17-hydroxyprogesterone (17-OHP) aims to identify patients with nonclassic CAH. However, confirmation of this diagnosis can be difficult due to the overlapping values among normal patients and heterozygote and homozygote carriers of mutations in the 21-hydroxylase (*CYP21A2*) gene. Accordingly, adrenal stimulation with ACTH, often colloquially termed the *cort stim test*, may be required as described in Chapter 18 (p. 398).

Other Serum Testing

At times, other serum testing may be prudent. If an eating disorder is suspected, an immediate assessment of serum electrolytes is warranted as imbalances can be life-threatening. An electrocardiogram also is considered in those patients perceived to have severe disease. A reverse triiodothyronine (T_3) level is often elevated in patients with functional hypothalamic amenorrhea. Women with PCOS are screened for insulin resistance and lipid abnormalities, as these are often found in affected patients and raise risks for diabetes and cardiovascular disease (Chap. 18, p. 399). Although no consensus exists, repeating these tests every few years in those with PCOS is sound practice.

Many patients with POI will not have a clear etiology for their disorder based on medical history or genetic testing and may reasonably be assumed to have an autoimmune cause. Current recommendations focus on measurement of antiadrenal antibodies, specifically antibodies directed against 21-hydroxylase. Addition of antithyroid antibodies such as antimicrosomal/thyroid peroxidase antibodies (TPOAb) also is logical if thyroid dysfunction is suspected.

Chromosomal Analysis

Patients with gonadal dysgenesis, such as Turner syndrome, are considered for chromosomal analysis. Classic teaching suggests that this test is unnecessary after age 30. However, consideration is given to testing patients up to age 35 because a rare individual mosaicism may retain functional oocytes and thus sustain cyclic menses longer than expected. As previously indicated, a Y-containing cell line requires bilateral oophorectomy because of the higher risk for ovarian germ cell tumors. Due to the close association between stature and abnormalities in the X chromosome, many specialists advise karyotyping all women with POI who are shorter than 60 inches (Saenger, 2001). Chromosomal studies are also considered in any woman with a family history of POI. Analysis is generally performed using classic karyotype approaches. However, with the advent of advanced sequencing methods, whole genome sequencing or other deep sequencing approaches may be considered in select circumstances.

Radiologic Evaluation

Any patient with hypogonadotropic hypogonadism is assumed to have an anatomic CNS or pituitary gland abnormality until proven otherwise by MR imaging or CT scanning. Thus, functional hypothalamic amenorrhea due to stress, exercise, or eating disorder is a diagnosis of exclusion. Imaging is highly sensitive for identification of destructive disorders such as tumors or infiltrative diseases of the hypothalamus or pituitary gland. Although fundamentally normal, a subset of patients with genetic causes for Kallmann syndrome or IHH will demonstrate developmental defects of the hypothalamus, olfactory bulbs, or pituitary gland during MR imaging (Klingmuller, 1987).

Reproductive tract anatomic disorders can be evaluated with several modalities depending on the suspected cause. Sonographic examination is frequently useful as a first screen for a uterus deemed grossly normal by physical examination. HSG or SIS is excellent for the detection of intrauterine synechiae or developmental anomalies. Changing trends favor SIS unless information on tubal patency also is required. Three-dimensional (3-D) sonography and 3-D SIS also can add information. MR imaging is frequently used for delineation of more complex uterine structures, such as a noncommunicating or hypoplastic uterine horn. Imaging of congenital reproductive tract anomalies is discussed further in Chapter 19 (p. 420).

TREATMENT

Treatment of amenorrhea depends on its etiology and patient goals such as a desire to treat hirsutism or seek pregnancy. Anatomic abnormalities often require surgical correction, if possible, and are discussed in Chapter 19 (p. 421). Hypothyroidism is treated with thyroid hormone replacement, and a suggested dosage of levothyroxine is 1.6 μg/kg of body weight per day (Baskin, 2002). For most, a common starting dose is 50 to 100 μg of levothyroxine orally daily. TSH response is slow, and levels are rechecked 6 to 8 weeks following initiation. A TSH level in the lower range of normal is the therapeutic goal. If needed, the dose may be increased by an increment of 12.5 or 25 μg (Jameson, 2012). Women with hyperprolactinemia receive a dopamine agonist, such as bromocriptine or cabergoline. Macroadenomas may require surgery if secondary deficits such as visual changes are observed. Both medical and surgical specifics of pituitary disease treatment are found in Chapter 16 (p. 362).

Estrogen Replacement

This therapy is instituted in essentially every patient with hypogonadism to avoid osteoporosis. As in postmenopausal women, bone loss is accelerated in the first few years following estrogen deprivation. Thus, treatment is instituted quickly. Women with a uterus also require continuous or intermittent progesterone

administration to protect against endometrial hyperplasia or cancer (Chap. 22, p. 481). There is no consensus, however, on an optimal regimen in these patients. Importantly, an escalating estrogen dose regimen is used for patients who have amenorrhea due to pubertal delay and will promote normal breast development (Chap. 15, p. 331). For women in their 20s, some experts recommend higher doses of estrogen than is routinely given to postmenopausal women as this is a time of ongoing bone deposition. Frequently, it is easiest to prescribe COCs. Younger women may prefer this treatment as their friends may also use these pills, and in their minds, hormone replacement therapy may be associated with aging. Of note, bone health may not be fully protected by estrogen in patients with ongoing energy deficits from eating disorders (Gordon, 2017). Additionally, consensus is lacking on treatment duration in those with hypogonadism. For most individuals, continuation until approximately age 50, the usual age of menopause, seems reasonable (American College of Obstetricians and Gynecologists, 2017c).

Patients who have eating disorders or who exercise excessively will require behavior modification. In a patient with an eating disorder, psychiatric intervention is imperative due to the significant morbidity and mortality associated with this diagnosis (American Psychiatric Association, 2013; Michopoulos, 2013). Elite athletes may choose not to alter their exercise regimens and will therefore require estrogen treatment.

Polycystic Ovarian Syndrome

Treatment of women with PCOS may include cyclic or constant progesterone treatment as outlined in Chapter 18 (p. 400). Insulin-sensitizing agents such as metformin (Glucophage) may be indicated in those with diabetes mellitus. In women with hyperandrogenism due to PCOS, COCs and/or spironolactone are often warranted.

Depending on its severity, nonclassic CAH in some women may be treated with low-dose corticosteroids to partially block ACTH stimulation of adrenal function and thereby decrease adrenal androgen overproduction.

Infertility

Alternative approaches may be required in a patient who desires conception. Adequate treatment of hyperprolactinemia and thyroid disease typically results in ovulation and in normal fertility for most women. If clearly linked to infertility, anatomic abnormalities are surgically corrected whenever possible. However, depending on the type and severity of the abnormality, a surrogate to carry a gestation may be needed. Although uterine transplantation followed by successful birth has been reported, this currently remains highly experimental (American Society for Reproductive Medicine, 2018). Stem cells also have been proposed for POI, but loss of ovarian reserve is best considered irreversible at present. Affected individuals can be offered in vitro fertilization using a donor oocyte to conceive. Assuming that behavioral modification is not successful, women with hypogonadotropic hypogonadism are referred to an infertility specialist for treatment with gonadotropins. Women with PCOS will frequently ovulate following treatment with the selective estrogen-receptor modulator clomiphene citrate or with an aromatase inhibitor such as letrozole. Clomiphene citrate is believed to act by transient inhibition of estrogen feedback at the hypothalamus and pituitary gland (Fig. 21-1, p. 452). This treatment, however, is not effective in those with hypogonadotropic hypogonadism as they lack significant levels of circulating estrogen.

Patient Education

Patients are adequately counseled regarding their diagnosis, its long-term implications, and treatment options. All women with an intact endometrium must understand the risks of unopposed estrogen action, whether the estrogen is exogenous, such as through hormone therapy, or endogenous, such as in PCOS. For hypoestrogenic women, clinicians explain the importance of estrogen replacement to protect against bone loss. As detailed in Chapter 22 (p. 502), estrogen may have additional benefits. Last, even if not raised by the patient, the potential or lack of potential for future child-bearing is discussed.

CHAPTER 18

Polycystic Ovarian Syndrome and Hyperandrogenism

DEFINITION 389
INCIDENCE AND ETIOLOGY 390
PATHOPHYSIOLOGY 390
SIGNS AND SYMPTOMS 392
DIAGNOSIS 396
TREATMENT 400
REFERENCES 402

Polycystic ovarian syndrome (PCOS) is a common endocrinopathy typified by oligoovulation or anovulation, signs of androgen excess, and an excess of small ovarian cysts. These signs and symptoms vary widely between women and within individuals over time. Women with this endocrine disorder also have higher rates of obesity, dyslipidemia, and insulin resistance, which raise long-term health risks. As a result, women with PCOS may first present to various medical specialists, including pediatricians, gynecologists, internists, endocrinologists, or dermatologists.

DEFINITION

Polycystic Ovarian Syndrome

In 2003 in Rotterdam, The Netherlands, PCOS in adults was redefined in a consensus meeting between the European Society of Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM)—The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004. As shown in Table 18-1, affected individuals must meet two out of three criteria. However, because other etiologies, such as congenital adrenal hyperplasia, androgen-secreting tumors, and hyperprolactinemia, also may lead to oligoovulation and/or androgen excess, these must be excluded. Thus, PCOS currently is a diagnosis of exclusion.

The Rotterdam criteria constitute a broader spectrum than that formerly put forward by the National Institutes of Health (NIH) Conference in 1990 (Zawadzki, 1990). The prominent difference is that the NIH Conference defined PCOS without regard to ovarian sonographic appearance. A third organization—The Androgen Excess and PCOS Society (AE-PCOS)—also has defined criteria for PCOS (Azziz, 2006). Subsequently, an NIH (2012) workshop emphasized the variable presentation of PCOS. Their consensus recommended the 2003 Rotterdam criteria be used to assign one of four specific patient phenotypes (see Table 18-1).

Importantly, these same criteria are not appropriate for adolescents. Guidance regarding specific criteria and thresholds are found later in those specific sections. In sum, the diagnosis of PCOS in adolescence is challenging because many symptoms of PCOS mimic the normal physiologic responses of puberty. For adolescents with incomplete criteria for a firm diagnosis of PCOS, careful surveillance is warranted as they may be diagnosed at a later time (Carmina, 2010; Witchel, 2015).

TABLE 18-1. Definition of PCOS

ESHRE/ASRM (Rotterdam) 2003
Two of the three:
- Clinical and/or biochemical hyperandrogenism (HA)
- Oligo-/anovulation (OA)
- Polycystic ovarian morphology (PCOM)[a]

NIH (1990)
To include both:
- Clinical and/or biochemical hyperandrogenism
- Oligo-/anovulation

AE-PCOS (2006)
To include both:
- Clinical and/or biochemical hyperandrogenism
- Oligo-/anovulation and/or polycystic ovarian morphology

NIH (2012)
To identify one of four phenotypes using Rotterdam criteria
- HA + OA + PCOM
- HA + OA
- HA + PCOM
- OA + PCOM

[a]Polycystic ovarian morphology identified by transvaginal sonography.
AE-PCOS = Androgen Excess and PCOS Society; ASRM = American Society of Reproductive Medicine; ESHRE = European Society of Human Reproduction and Embryology; NIH = National Institutes of Health. PCOS = polycystic ovarian syndrome.

Ovarian Hyperthecosis and HAIRAN Syndrome

Ovarian hyperthecosis, often considered a more severe form of PCOS, is a rare condition characterized by nests of luteinized theca cells distributed throughout the ovarian stroma. Affected women exhibit severe hyperandrogenism and greater degree of insulin resistance (Nagamani, 1986, 1999).

Hyperandrogenic-insulin resistant-acanthosis nigricans (HAIRAN) syndrome also is uncommon and consists of marked hyperandrogenism, severe insulin resistance, and acanthosis nigricans (Barbieri, 1983). Both conditions are exaggerated PCOS phenotypes, and their treatment mirrors that for PCOS.

INCIDENCE AND ETIOLOGY

PCOS is the most common endocrine disorder of reproductive-aged women and affects approximately 6 to 16 percent in general population studies (Li, 2013; Lizneva, 2016). Although symptoms of androgen excess may vary among ethnicities, PCOS appears to affect all races and nationalities similarly.

The underlying cause of PCOS is unknown. However, a genetic basis that is both multifactorial and polygenic is suspected, as the syndrome aggregates within families and first-degree relatives (Kahsar-Miller, 2001; Yildiz, 2003). Twin studies also implicate a prominent heritable influence (Vink, 2006).

Some have suggested an autosomal dominant inheritance with expression in both females and males. First-degree male relatives of women with PCOS have significantly higher rates of elevated circulating dehydroepiandrosterone sulfate (DHEAS) levels, early balding, and insulin resistance compared with male controls (Legro, 2000, 2002). Other metabolic alterations typical for PCOS also are found in greater frequency in male relatives (Cannarella, 2018; Liu, 2014; Torchen, 2016).

Several risk loci have been identified by genome-wide association studies in women with PCOS (Day, 2018; Zhao, 2016). Putative genes include those involved in androgen synthesis, obesity, and insulin resistance (Mykhalchenko, 2017). In addition, epigenetic modification of genetic susceptibility within the maternal-fetal environment may influence adult PCOS development (Dumesic, 2014).

PATHOPHYSIOLOGY

Gonadotropins

Anovulation in women with PCOS is characterized by inappropriate gonadotropin secretion (Fig. 18-1). Specifically, altered gonadotropin-releasing hormone (GnRH) pulsatility leads to preferential production of luteinizing hormone (LH) compared with follicle-stimulating hormone (FSH) (Hayes, 1998; Waldstreicher, 1988). It is currently unknown whether hypothalamic dysfunction is a primary cause of PCOS or is secondary to abnormal steroid feedback. In either case, serum LH levels rise, and elevated levels are observed clinically in approximately 50 percent of affected women (van Santbrink, 1997). Similarly, LH: FSH ratios are elevated and rise above 2:1 in approximately 60 percent of patients (Rebar, 1976).

TABLE 18-2. Consequences of Polycystic Ovarian Syndrome

Short-term consequences
Obesity
Infertility
Sleep apnea
Irregular menses
Depression/anxiety
Abnormal lipid levels
Non-alcoholic fatty liver disease
Hirsutism/acne/androgenic alopecia
Insulin resistance/acanthosis nigricans
Long-term consequences
Diabetes mellitus
Endometrial cancer
Cardiovascular disease

Insulin Resistance

Women with PCOS also display greater degrees of insulin resistance and compensatory hyperinsulinemia than nonaffected women. Insulin resistance is defined as a reduced glucose-uptake response to a given amount of insulin. This lower insulin sensitivity appears to stem from a postbinding abnormality in insulin receptor–mediated signal transduction (Dunaif, 1997). Both lean and obese women with PCOS are found to be more insulin resistant than nonaffected weight-matched controls (Dunaif, 1989, 1992).

Insulin resistance is associated with several disorders including type 2 diabetes mellitus (DM), hypertension, dyslipidemia, and cardiovascular disease (CVD). Therefore, PCOS is not simply a disorder of short-term consequences such as irregular menses and hirsutism, but also one of potential long-term health consequences (Table 18-2).

Androgens

Both insulin and LH stimulate androgen production by the ovarian theca cell (Dunaif, 1992). As a result, affected ovaries secrete elevated levels of testosterone and androstenedione. Specifically, elevated free testosterone levels are noted in 70 to 80 percent of women with PCOS, and 25 to 65 percent exhibit elevated levels of DHEAS (Moran, 1994, 1999; O'Driscoll, 1994). In turn, elevated androstenedione levels contribute to greater estrone levels through peripheral conversion of androgens to estrogens by aromatase.

Sex Hormone–Binding Globulin

Women with PCOS display decreased levels of sex hormone–binding globulin (SHBG). This glycoprotein, produced in the liver, binds most sex steroids. Only approximately 1 percent of these steroids are unbound and thus free and bioavailable. The synthesis of SHBG is suppressed by insulin and by androgens, corticoids, progestins, and growth hormone (Bergh, 1993). Because of suppressed SHBG production, less circulating

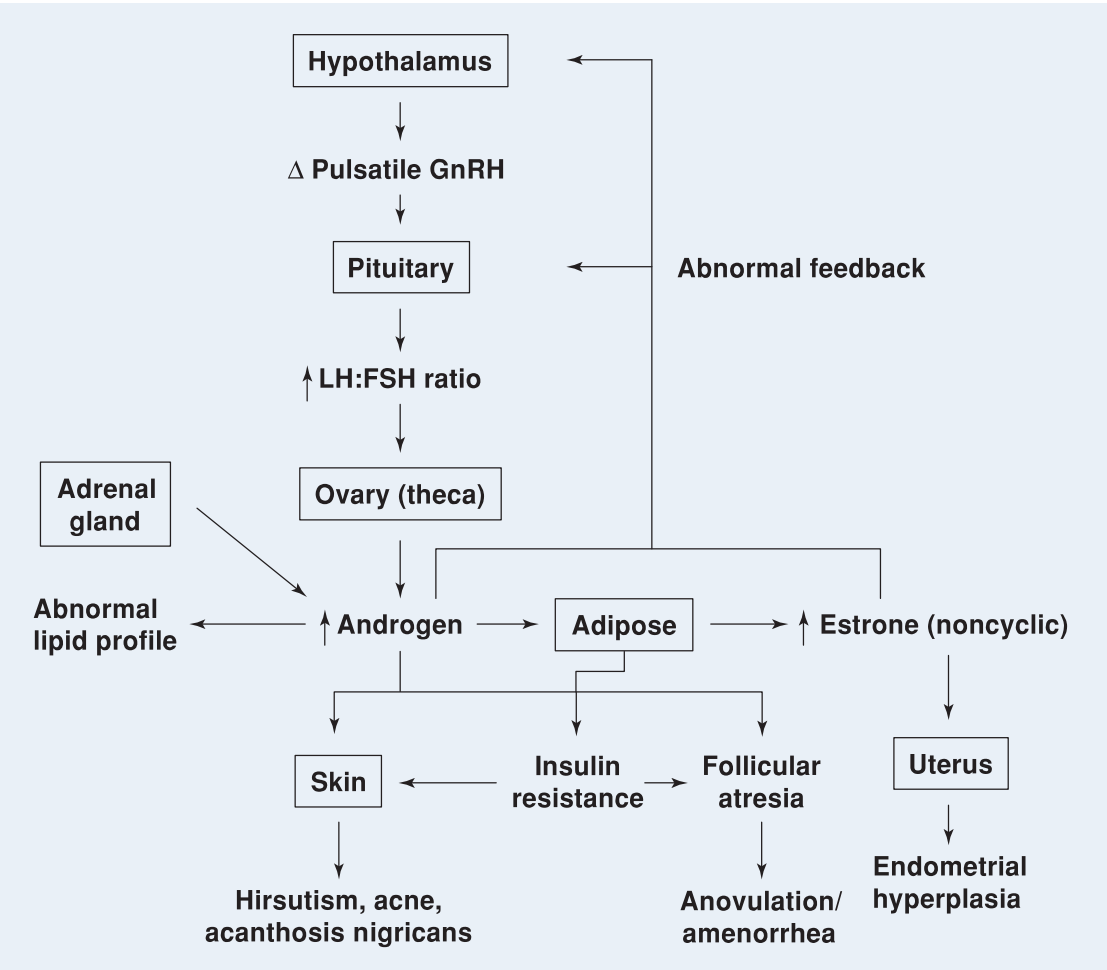

FIGURE 18-1 Model for the initiation and maintenance of polycystic ovarian syndrome (PCOS). Alterations in pulsatile gonadotropin-releasing hormone (GnRH) release may lead to a relative increase in luteinizing hormone (LH) versus follicle-stimulating hormone (FSH) biosynthesis and secretion. LH stimulates ovarian androgen production, while the relative paucity of FSH prevents adequate stimulation of aromatase activity within the granulosa cells, thereby decreasing androgen conversion to the potent estrogen estradiol.

Increased intrafollicular androgen levels result in follicular atresia. Increased circulating androgen levels contribute to abnormalities in patient lipid profiles and the development of hirsutism and acne. Increased circulating androgens can also be derived from the adrenal gland.

Elevated serum androgens (primarily androstenedione) are converted in the periphery to estrogens (primarily estrone). As conversion occurs primarily in the stromal cells of adipose tissue, estrogen production will be augmented in obese PCOS patients. This conversion results in chronic feedback at the hypothalamus and pituitary gland, in contrast to the normal fluctuations in feedback observed in the presence of a growing follicle and rapidly changing levels of estradiol. Unopposed estrogen stimulation of the endometrium may lead to endometrial hyperplasia.

Insulin resistance due to genetic abnormalities and/or increased adipose tissue contributes to follicular atresia in the ovaries as well as the development of acanthosis nigricans in the skin.

Lack of follicular development results in anovulation and subsequent oligo- or amenorrhea.

Note that this syndrome may develop from primary dysfunction of any one of a number of organ systems. For example, elevated ovarian androgen production may be due to either an intrinsic abnormality in enzymatic function and/or abnormal hypothalamic-pituitary stimulation with LH and FSH.

The common denominator is development of a self-perpetuating noncyclic hormonal pattern.

androgen is bound and thus more remains available to bind with end-organ receptors. Accordingly, some women with PCOS will have total testosterone levels in the normal range but will be clinically hyperandrogenic due to elevated free testosterone levels.

In addition to hyperandrogenism, low SHBG levels also have been linked to impaired glucose control and a risk for developing type 2 DM (Ding, 2009). The mechanism of this association is not fully understood and may reflect a role for SHBG in glucose homeostasis. For example, Veltman-Verhulst (2010) evaluated SHBG levels in women with PCOS and found an association between low SHBG levels and subsequent development of gestational diabetes mellitus.

Anovulation

The precise mechanism leading to anovulation is unclear. First, altered GnRH pulsatility and inappropriate gonadotropin secretion are implicated in menstrual irregularity.

Moreover, anovulation may result from insulin resistance, as a substantial number of anovulatory patients with PCOS may resume ovulatory cycles when treated with metformin, an insulin sensitizer (Nestler, 1998). It has been suggested that oligoovulatory women with PCOS exhibit a milder phenotype of ovarian dysfunction than anovulatory PCOS patients and have a more favorable response to ovulation induction agents (Burgers, 2010).

Last, the large antral follicle cohort and associated higher intraovarian androgen levels seen in PCOS may contribute to anovulation. This is supported by the fact that some patients who have undergone ovarian wedge resection or laparoscopic ovarian drilling have improved menstrual regularity. One study demonstrated that 67 percent of PCOS patients developed regular menses following such surgery compared with only 8 percent prior to surgery (Amer, 2002).

SIGNS AND SYMPTOMS

In women with PCOS, symptoms may include menstrual irregularities, infertility, manifestations of androgen excess, or other endocrine dysfunction. Symptoms classically become apparent within a few years of puberty.

Menstrual Dysfunction

In women with PCOS, menstrual dysfunction may range from amenorrhea to oligomenorrhea to episodic heavy menstrual bleeding with associated iron-deficiency anemia. In most cases, amenorrhea and oligomenorrhea result from anovulation. Namely, without ovulation and endogenous progesterone production from the corpus luteum, a normal menstrual period is not triggered.

Instead, chronic estrogen exposure results and produces constant mitogenic stimulation of the endometrium. The instability of the thickened endometrium leads to unpredictable bleeding.

Oligomenorrhea (fewer than nine menstrual periods in 1 year) or amenorrhea (absence of menses for 3 or more consecutive months) with PCOS usually begins with menarche (American Society for Reproductive Medicine, 2008). Those with PCOS fail to establish monthly ovulatory menstrual cycles by midadolescence, and they often continue to have irregularity. Notably, many postmenarchal girls have irregular periods because of hypothalamic-pituitary-ovarian axis immaturity. However, lack of menarche by age 15 years or within 3 years of thelarche merits evaluation for delayed puberty (Chap. 15, p. 331) (American College of Obstetricians and Gynecologists, 2017). Factoring clinical context, menstrual intervals <20 days or >45 days in girls ≥ 2 years after menarche or menstrual interval >90 days any time after menarche merits consideration of further evaluation (Witchel, 2015).

As women with PCOS age, those with prior irregular cycle intervals may develop regular cycle patterns. A decreasing antral follicle cohort as women enter their 30s and 40s may lead to a concurrent decrease in androgen production (Elting, 2000).

Last, amenorrhea can stem from elevated androgen levels. Specifically, androgens can counteract estrogen to produce an atrophic endometrium. Thus, with markedly elevated androgen levels, amenorrhea and a thin endometrial stripe can be seen.

Hyperandrogenism

This condition is usually manifested clinically by hirsutism, acne, and/or androgenic alopecia. In contrast, signs of virilization such as increased muscle mass, voice deepening, and clitoromegaly are not typical of PCOS. Virilization reflects higher androgen levels and should prompt investigation for an androgen-producing tumor of the ovary or adrenal gland.

Hirsutism

In a female, hirsutism is defined as coarse, dark, terminal hairs distributed in a male pattern (Fig. 18-2). This is distinguished from hypertrichosis, which is a generalized increase in lanugo, that is, the soft, lightly pigmented hair associated with some medications and malignancies. PCOS accounts for 70 to 80 percent of cases of hirsutism, which typically begins in late adolescence or the early 20s. Idiopathic hirsutism is the second most frequent cause (Azziz, 2003). Additionally, various drugs may lead to hirsutism, and their use should be investigated (Table 18-3).

FIGURE 18-2 **A.** Facial hirsutism. (Reproduced with permission from Dr. Tamara Chao.) **B.** Male pattern escutcheon.

TABLE 18-3. Medications That May Cause Hirsutism and/or Hypertrichosis

Hirsutism	Hypertrichosis
Anabolic steroids	Cyclosporine
Danazol	Diazoxide
Metoclopramide	Hydrocortisone
Methyldopa	Minoxidil
Phenothiazines	Penicillamine
Progestins	Phenytoin
Reserpine	Psoralens
Testosterone	Streptomycin

Pathophysiology of Hirsutism. Elevated androgen levels play a major role in determining the type and distribution of hair. Within a hair follicle, testosterone is converted by the enzyme 5α-reductase to dihydrotestosterone (DHT) (Fig. 18-3). Although both testosterone and DHT convert short, soft vellus hair to coarse terminal hair, DHT is markedly more effective than testosterone. Conversion is irreversible, and only hairs in androgen-sensitive areas are changed in this manner to terminal hairs. As a result the most common areas affected with excess hair growth include the upper lip, chin, sideburns, chest, and linea alba of the lower abdomen. Specifically, *escutcheon* is the term used to describe the hair pattern of the lower abdomen. In unaffected women, this pattern is triangular and overlies the mons pubis, whereas in men it extends up the linea alba to form a diamond shape.

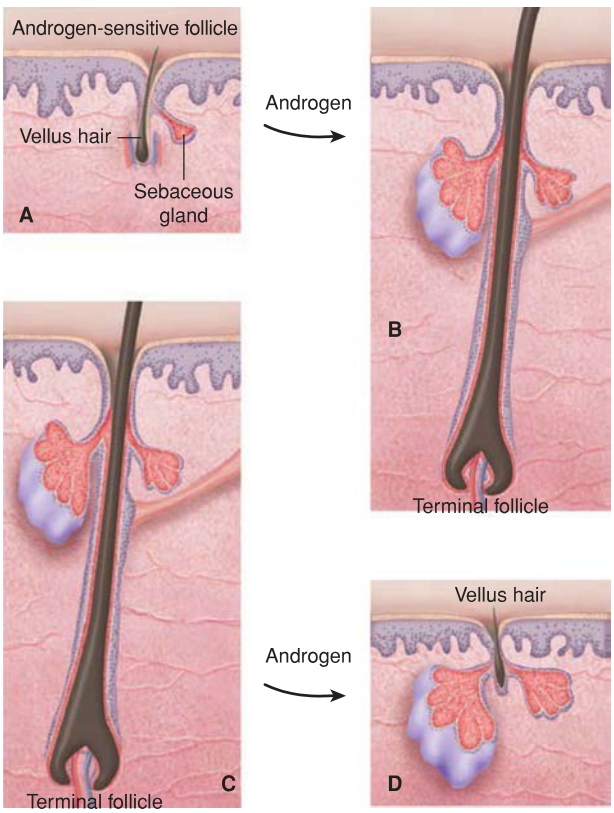

FIGURE 18-3 Androgenic effects on the pilosebaceous unit. In some hair-bearing areas, androgens stimulate sebaceous glands, and vellus follicles **(A)** are converted to terminal follicles **(B)**, leading to hirsutism. Under the influence of androgens, terminal hairs that were not previously dependent on androgens **(C)** revert to a vellus form and balding results **(D)**.

The concentration of hair follicles per unit area does not differ between men and women, however, racial and ethnic differences do exist. Individuals of Mediterranean descent have a higher concentration of hair follicles than Northern Europeans, and a much higher concentration than Asians. For this reason, Asians with PCOS are much less likely to present with overt hirsutism than other ethnic groups. Additionally, the familial tendency for hirsutism development is strong and stems from genetic differences in 5α-reductase activity and in target tissue sensitivity to androgens.

Ferriman-Gallwey Scoring System. To quantify the degree of hirsutism for research purposes, the Ferriman-Gallwey scoring system was developed in 1961 and later modified in 1981 (Ferriman, 1961; Hatch, 1981). Within this system, abnormal hair distribution is assessed in nine body areas and scored from 0 to 4 (Fig. 18-4). Increasing numeric scores correspond to greater hair density within a given area. Many investigators define hirsutism as a score ≥4 to 6 using the modified scoring (Teede, 2019). Because of the lower follicle concentration in Far East Asians, the AE-PCOS Society suggests a threshold value ≥3 for this group (Escobar-Morreale, 2012).

The Ferriman-Gallwey scoring system is cumbersome and thus is not used frequently in clinical settings. Nevertheless, it may be useful for following treatment responses in individual patients. Alternatively, an abbreviated score that combines only the upper and lower abdomen and chin scores may be a suitable surrogate (Cook, 2011). Also, many specialists choose to classify hirsutism more generally as mild, moderate, or severe depending on the location and density of hair growth.

Acne

Mild to moderate acne vulgaris is a frequent clinical finding in adolescents. However, acne that is persistent, moderate to severe, or late onset raises concern for PCOS or other androgen excess source (Homburg, 2004; Witchel, 2015). The prevalence of acne in women with PCOS is unknown, although one study found that 50 percent of adolescents with PCOS have moderate acne (Dramusic, 1997). In addition, androgen level elevation has been reported in 80 percent of women with severe acne, 50 percent with moderate acne, and 33 percent with mild acne (Bunker, 1989). Women with moderate to severe acne have an increased prevalence (52 to 83 percent) of polycystic ovaries identified during sonographic examination (Betti, 1990; Bunker, 1989).

The pathogenesis of acne vulgaris involves four factors: blockage of the follicular opening by hyperkeratosis, sebum overproduction, proliferation of commensal *Propionibacterium acnes*, and inflammation. As in the hair follicle, testosterone is converted within sebaceous glands to its more active metabolite, DHT, by 5α-reductase. In women with androgen excess, overstimulation of androgen receptors in the pilosebaceous unit elevates sebum production that eventually leads to inflammation

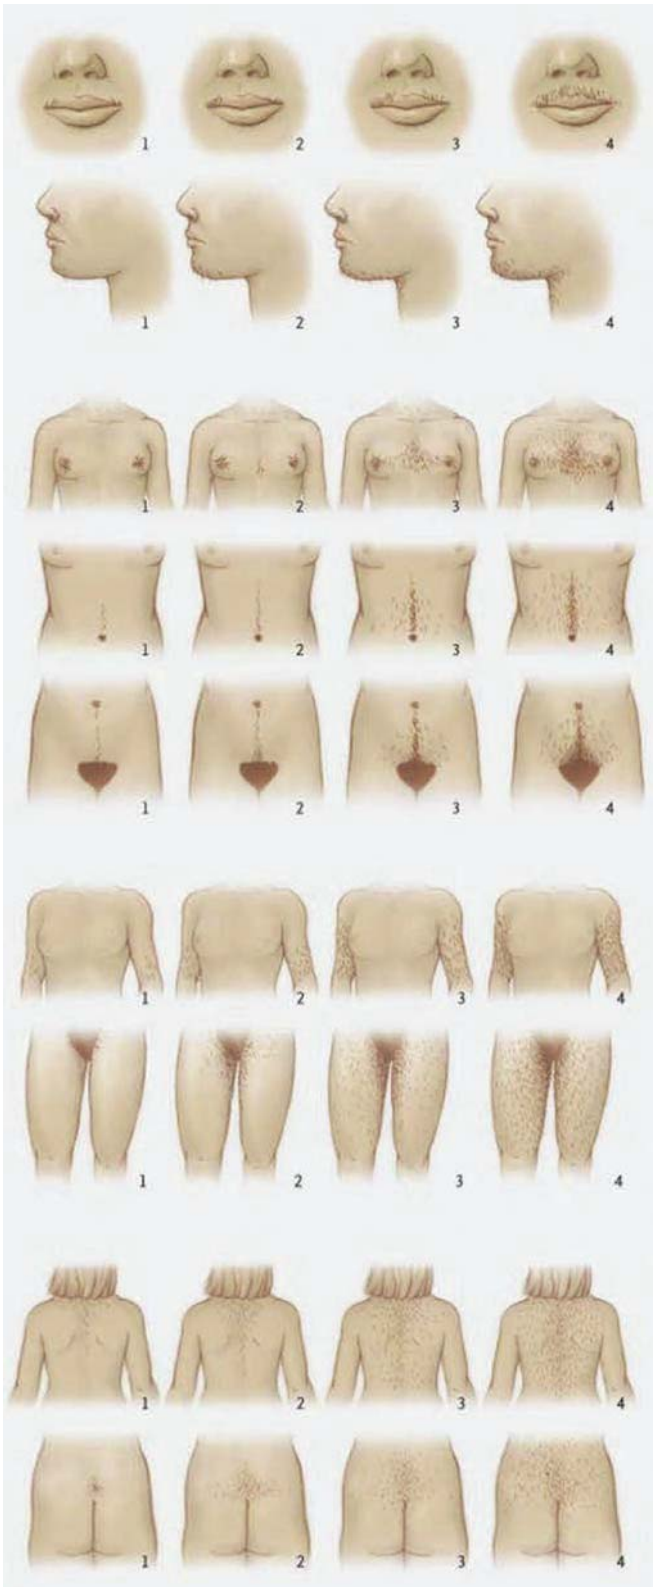

FIGURE 18-4 Depiction of the Ferriman-Gallwey system for scoring hirsutism.

and comedone formation (see Fig. 18-3). Inflammation leads to the main long-term side effect of acne—scarring. Accordingly, treatment is directed at minimizing inflammation, decreasing keratin production, lowering colonization of *P acnes*, and reducing androgen levels to diminish sebum production.

Alopecia

Female androgenic alopecia is a less common finding in women with PCOS. Hair slowly thins diffusely at the crown, but the frontal hairline is preserved (Quinn, 2014). Of the several available scoring methods, the three-grade Ludwig visual score is a recommended (Teede, 2019). The perceptible thinning of grade I progressively worsens to total balding of the crown in grade III (Gupta, 2016).

Alopecia pathogenesis involves an excess of 5α-reductase activity in the hair follicle leading to a rise in DHT levels. Moreover, androgen receptor expression in these individuals is increased (Chen, 2002). Alopecia, however, may reflect other serious disease. For this reason, affected women are also evaluated to exclude thyroid dysfunction, anemia, or other chronic illness (Levy, 2013).

Other Endocrine Dysfunction

Insulin Resistance

The precise incidence of insulin resistance in women with PCOS has been difficult to ascertain for lack of a simple method to determine insulin sensitivity in an office setting. Although obesity is known to exacerbate insulin resistance, one classic study demonstrated that both lean and obese women with PCOS have higher rates of insulin resistance and type 2 DM compared with weight-matched controls without PCOS (Fig. 18-5) (Dunaif, 1989, 1992).

Acanthosis Nigricans. In this skin condition, thick, gray-brown velvety plaques develop in flexure areas such as the back of the neck, axillae, inframammary creases, waist, and groin (Fig. 18-6) (Panidis, 1995). Thought to be a cutaneous marker of insulin resistance, acanthosis nigricans may be found in individuals with or without PCOS. Insulin resistance leads to hyperinsulinemia, which is believed to stimulate keratinocyte and dermal fibroblast growth, producing the characteristic skin changes (Cruz, 1992). Indeed, in one cohort of 237 women with PCOS, acanthosis nigricans was found in 70 percent of those with the metabolic syndrome and in 45 percent without metabolic syndrome (Kazemi, 2019). In another study of women with PCOS, the rate of acanthosis nigricans in obese

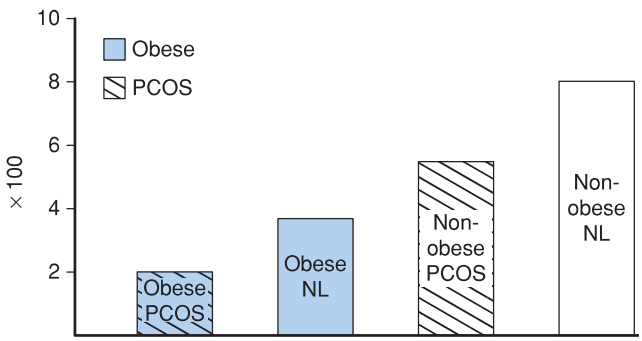

FIGURE 18-5 Insulin sensitivity is decreased in obese women with polycystic ovarian syndrome. NL = normal (those without PCOS); PCOS = polycystic ovarian syndrome. (From Dunaif, 1989, with permission.)

FIGURE 18-6 Acanthosis nigricans and multiple small pedunculated acrochordons (skin tags) in the neck crease. Both are dermatologic signs of insulin resistance.

woman was more than twice the rate in normal-weight women (Reyes-Muñoz, 2016).

Rarely, it is seen with genetic syndromes or gastrointestinal tract malignancy, such as adenocarcinoma of the stomach or pancreas. To differentiate, acanthosis nigricans associated with malignancy usually has a more abrupt onset, and skin involvement is more extensive (Moore, 2008).

Optimal treatment for acanthosis nigricans is directed toward decreasing insulin resistance and hyperinsulinemia. Topical retinoids are a first-line adjunct option (Patel, 2018).

Impaired Glucose Tolerance and Type 2 Diabetes Mellitus. Women with PCOS are at increased risk for impaired glucose tolerance (IGT) and type 2 DM. Based on oral glucose tolerance testing of obese women with PCOS, the prevalence of IGT and DM approximates 30 percent and 7 percent, respectively (Legro, 1999). Even after adjusting for body mass index (BMI), women with PCOS remained more likely to have DM (Lo, 2006). Specifically, β-cell dysfunction that is independent of obesity has been reported in patients with PCOS (Dunaif, 1996). Similar findings are reported in groups of obese and normal-weight adolescent girls with PCOS (Flannery, 2013; Palmert, 2002).

Dyslipidemia

The classic atherogenic lipoprotein profile seen in PCOS shows increased low-density lipoprotein (LDL) and triglyceride levels, elevated total cholesterol:high-density lipoprotein (HDL) ratios, but depressed HDL levels (Banaszewska, 2006; Wild, 2011). Independent of total cholesterol levels, these changes may raise the cardiovascular disease risk in women with PCOS. The prevalence of dyslipidemia in PCOS approaches 70 percent (Legro, 2001; Talbott, 1998).

Obesity

Compared with age-matched controls, women with PCOS are more likely to be obese, as reflected by elevated BMIs and waist:hip ratios (Talbott, 1995). This ratio reflects an android or central pattern of obesity, which itself is an independent risk factor for CVD and predicts insulin resistance. As noted earlier, insulin resistance is believed to play a large role in the pathogenesis of PCOS and is often exacerbated by obesity (Dunaif, 1989). For example, obesity can exacerbate hyperandrogenism by lowering SHBG levels and thereby raise bioavailable testosterone levels (Lim, 2013). Thus, obesity can have a synergistic effect on PCOS and can worsen ovulatory dysfunction, hyperandrogenism, and acanthosis nigricans.

Obstructive Sleep Apnea

In the general population, obstructive sleep apnea is related to central obesity (Peppard, 2000; Senaratna, 2017). Of women with PCOS, 35 percent had obstructive sleep apnea in one metaanalysis, especially obese women with PCOS (Kahal, 2019). However, some evidence suggests that some PCOS metabolic changes also may be contributory (Gopal, 2002; Tasali, 2008; Vgontzas, 2001). For example, women with PCOS have significantly higher risk of sleep apnea compared with weight-matched controls (Fogel, 2001).

Metabolic Syndrome and Cardiovascular Disease

The metabolic syndrome is characterized by insulin resistance, obesity, atherogenic dyslipidemia, and hypertension. It is associated with a greater risk of CVD and type 2 DM (Schneider, 2006). The prevalence of metabolic syndrome approximates 45 percent in women with PCOS compared with 4 percent in age-adjusted controls (Fig. 18-7) (Dokras, 2005). PCOS shares several endocrine features with the metabolic syndrome, although definitive evidence for an increased incidence of CVD in women with PCOS is lacking (Legro, 1999; Rebuffe-Scrive, 1989; Talbott, 1998). However, in a small group of women with PCOS, Dahlgren and colleagues (1992) predicted a relative risk of 7.4 for myocardial infarction. Another 10-year surveillance study showed an odds ratio of 6 for CVD in overweight white women with PCOS (Talbott, 1995). Thus, evidence suggests that women with PCOS should have CVD factors identified and treated (Table 1-10, p. 16) (Goodman, 2015; Teede, 2019).

Endometrial Neoplasia

In women with PCOS, the risk of endometrial cancer is increased three- to fourfold (Barry, 2014; Haoula, 2012; Gottschau, 2015). Endometrial hyperplasia and endometrial cancer are long-term risks of chronic anovulation, and neoplastic changes in the endometrium are felt to arise from chronic unopposed estrogen (Chap. 33, p. 699). Moreover, the effects of hyperandrogenism, hyperinsulinemia, and obesity to lower SHBG levels and raise circulating estrogen levels may add to this risk.

Few women who develop endometrial cancer are younger than 40 years, and most of these premenopausal women are

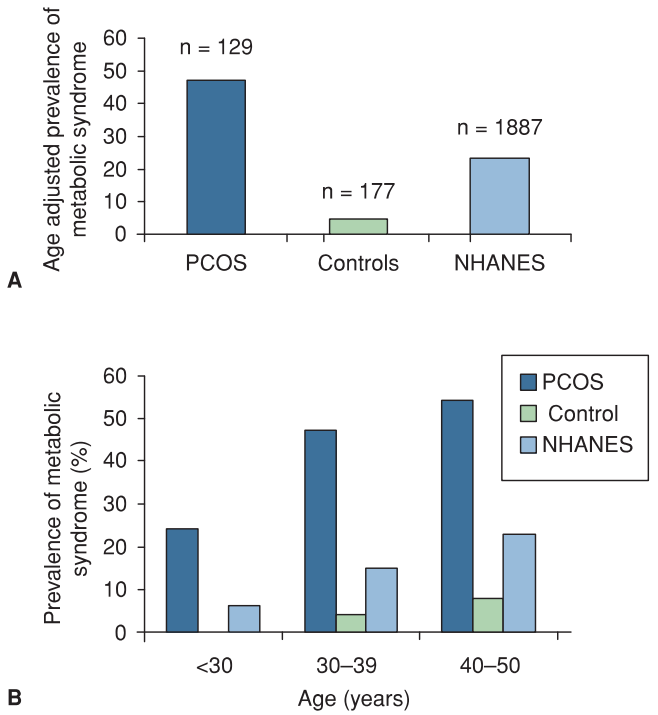

FIGURE 18-7 A. Women with polycystic ovarian syndrome (PCOS) have an increased risk of metabolic syndrome compared with age-adjusted controls and with women from the Third National Health and Nutrition Survey (NHANES III). **B.** In women with PCOS, the risk of metabolic syndrome begins earlier than in controls or those from NHANES III. NHANES III collected data from a representative sample of the noninstitutionalized civilian U.S. population from 1988 through 1994. (From Dokras, 2005, with permission.)

obese or have chronic anovulation or both (National Cancer Institute, 2019). Thus, the American College of Obstetricians and Gynecologists (2016) recommends endometrial assessment in any woman older than 45 years with abnormal uterine bleeding. In addition, those younger than 45 years with a history of unopposed estrogen exposure such as seen in obesity or PCOS, those with failed medical management, and women with persistent bleeding are ideally sampled. Steps of this procedure are found in Chapter 8 (p. 183).

Infertility

Infertility or subfertility is a frequent complaint in women with PCOS and results from anovulatory cycles. Moreover, in women with infertility secondary to anovulation, PCOS is a common cause. Infertility evaluation and treatment in PCOS-affected women is described in more detail in Chapter 21 (p. 453).

Complications in Pregnancy

Women with PCOS who become pregnant experience a higher rate (30 to 50 percent) of early miscarriage compared with a baseline rate of approximately 15 percent in the general population (Homburg, 1998; Regan, 1990; Sagle, 1988). The etiology of early miscarriage in women with PCOS is unclear. Obesity, which is commonly comorbid with PCOS, is implicated. For example, in one large longitudinal study, overweight and obese women with PCOS suffered higher miscarriage rates, whereas a normal-weight group with PCOS did not (Joham, 2014a). Others have suggested that insulin resistance is related to miscarriage in women with PCOS. In response to this, metformin (Glucophage), an insulin level–lowering drug, has been investigated. However, a metaanalysis of 17 studies failed to show an effect of metformin administration on miscarriage risk in women with PCOS (Palomba, 2009).

Of other pregnancy complications, higher risks of gestational diabetes, pregnancy-induced hypertension, and preterm birth have been noted (Bahri Khomami, 2019; Naver, 2014; Palomba, 2015). Gestational diabetes risk persists independently of weight but is enhanced by greater BMI (Joham, 2014b). Metformin has been studied as a tool to mitigate these complications in those with PCOS but without DM. However, investigators in one study found that metformin treatment during pregnancy did not reduce rates of these complications (Vanky, 2010).

Many women with PCOS require the use of ovulation induction medications or in vitro fertilization to conceive. These practices substantially raise the risk of multifetal gestations, which are associated with elevated rates of maternal and neonatal complications (Chap. 21, p. 457).

Psychologic Health

Women with PCOS may present with various psychosocial problems such as anxiety, depression, eating disorders, and negative body image (Deeks, 2011; Dokras, 2011, 2012; Lee, 2017). For those diagnosed with PCOS, screening for depression and anxiety is recommended (Dokras, 2018; Teede, 2019). Screening tools are found in Chapter 14 (p. 303). Similarly, if an eating disorder is suspected, an initial screen is recommended.

DIAGNOSIS

Other potentially serious disorders may clinically appear similar to PCOS and are excluded during patient evaluation (Table 18-4). For women who present with complaints of hirsutism, the algorithm in Figure 18-8 can be used.

Thyroid-Stimulating Hormone and Prolactin

Thyroid disease may frequently lead to menstrual dysfunction. Thus, a serum thyroid-stimulating hormone level is typically measured during evaluation, and treatment is discussed in Chapter 17 (p. 381). Similarly, hyperprolactinemia is a well-known cause of menstrual irregularities and occasionally amenorrhea. Elevated prolactin levels lead to anovulation through inhibition of GnRH pulsatile secretion. A list of potential causes of hyperprolactinemia is found in Table 13-2 (p. 285), and treatments are described in Chapter 16 (p. 362).

Testosterone and Dehydroepiandrosterone Sulfate

Tumors of the ovary or adrenal are a rare but serious cause of androgen excess. Various ovarian neoplasms, both benign and malignant, may produce testosterone and lead to virilization.

TABLE 18-4. Differential Diagnoses of Ovulatory Dysfunction and Hyperandrogenism

	Evaluation	Indicative Results[a]
Causes of oligo- or anovulation		
PCOS	Total T level	Mildly increased
	DHEAS level	May be mildly increased
	LH:FSH ratio	Typically >2:1
	AMH level	Increased
Hyperthyroidism	TSH level	Decreased
Hypothyroidism	TSH level	Increased
Hyperprolactinemia	PRL level	Increased
Hypogonadotropic hypogonadism	FSH, LH, E_2 levels	All decreased
POI	FSH, LH levels	Increased
	E_2 levels	Decreased
Causes of hyperandrogenism		
PCOS		
Late-onset CAH	17-OHP level	>200 ng/dL
Androgen-secreting ovarian tumor	Total T level	>200 ng/dL
Androgen-secreting adrenal tumor	DHEAS level	>700 µg/dL
Cushing syndrome	Cortisol level	Increased
Exogenous androgen use	Toxicology screen	Increased
Summary of PCOS testing		
Serum levels of FSH, LH, TSH, Total T, free T, estradiol, PRL,17-OH-P, DHEAS, 2-hr GTT, HbA_{1C}, lipid profile		
Measurement of BMI, waist circumference, BP		

[a]Based on reference laboratory ranges of normal.
AMH = antimüllerian hormone; BMI = body mass index; BP = blood pressure; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; E_2 = estradiol; FSH = follicle-stimulating hormone; GTT = glucose tolerance test; LH = luteinizing hormone; 17-OHP = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POI = premature ovarian insufficiency; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

Among others, these include the stromal tumors (Chap. 36, p. 764). Importantly, an abrupt onset or sudden worsening of virilizing signs should prompt concern for a hormone-producing ovarian or adrenal tumor (Fig. 18-9). Symptoms may include those in Table 18-5. Of these, hirsutism is quantified with the Ferriman-Gallwey score, whereas clitoromegaly is assessed using the clitoral index. For the latter, clitoral length (mm) and width (mm) values are multiplied. Values greater than 35 mm^2 are abnormal (Tagatz, 1979; Verkauf, 1992).

Diagnostically, serum testosterone levels can aid ovarian tumor exclusion. Free testosterone levels are more sensitive than total testosterone levels as an indicator of hyperandrogenism. Although improving, however, current free testosterone assays lack a uniform laboratory standard. For this reason, total testosterone levels remain the best approach for identifying a possible tumor. Threshold values >200 ng/dL of total testosterone warrant evaluation for an ovarian lesion (Derksen, 1994).

Pelvic sonography is the preferred method to exclude an ovarian neoplasm in a female with very high androgen levels. Alternatively, computed tomography (CT) or magnetic resonance (MR) imaging also may be used.

DHEAS is essentially produced exclusively by the adrenal gland. Therefore, serum DHEAS levels >700 µg/dL are highly suggestive of an adrenal neoplasm, and adrenal imaging with abdominal CT or MR imaging is warranted.

TABLE 18-5. Clinical Features of Virilization

Acne	Androgenic alopecia
Hirsutism	Decreased breast size
Amenorrhea	Deepening of the voice
Clitoromegaly	Increased muscle mass

Gonadotropins

During evaluation of amenorrhea, FSH, LH, and estradiol levels are typically measured to exclude premature ovarian insufficiency and hypogonadotropic hypogonadism (see Table 18-4). Although classically LH levels measure at least twofold higher than FSH levels, this is not found in all women with PCOS. Specifically, one third of women with PCOS have circulating LH levels in the normal range, a finding more common in obese patients (Arroyo, 1997; Taylor, 1997). Moreover, serum LH levels are affected by sample timing within a menstrual cycle, use of oral contraceptive pills, and BMI.

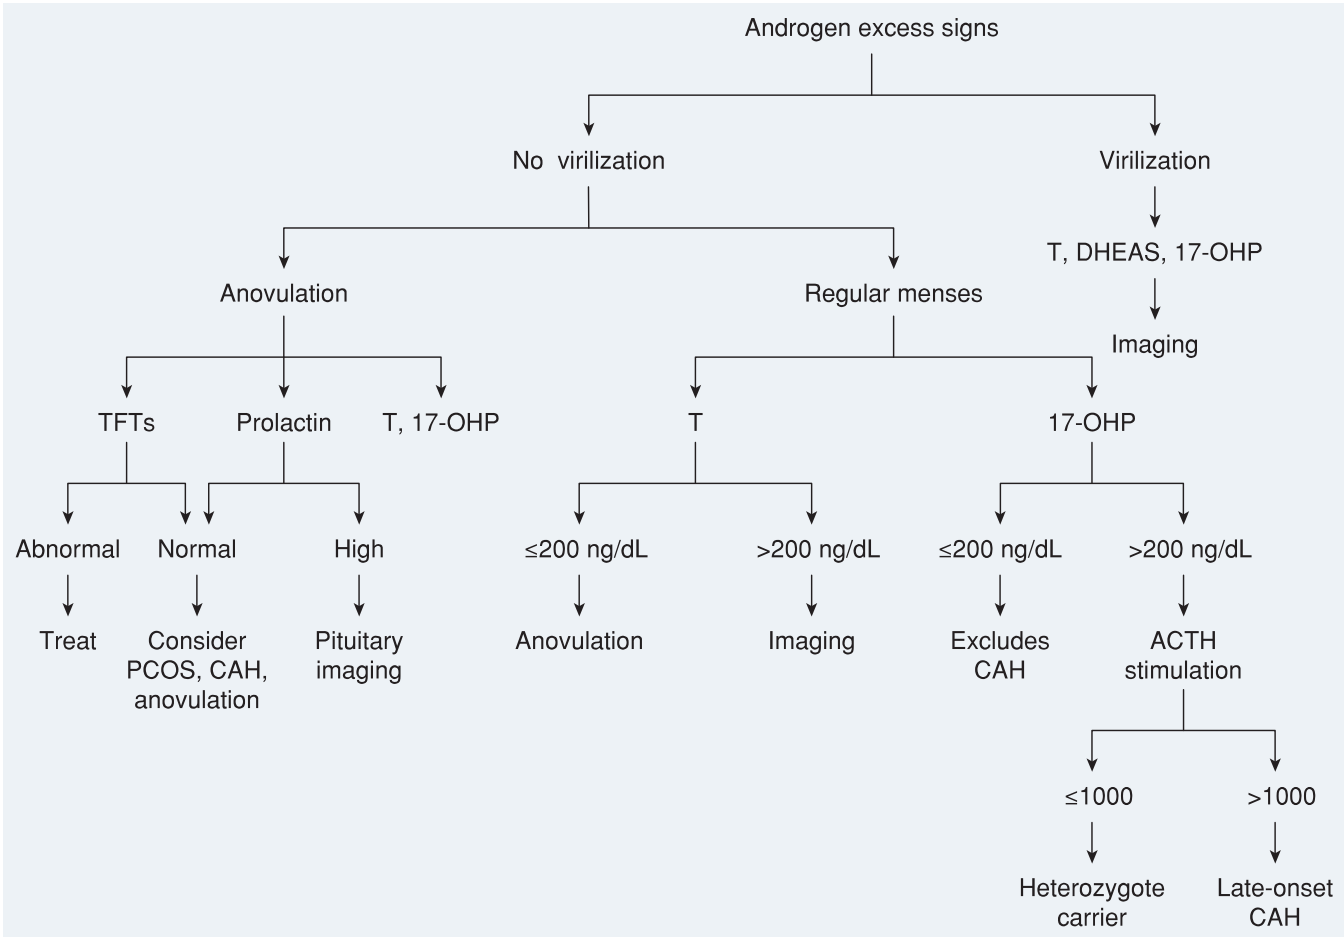

FIGURE 18-8 Algorithm for evaluation of androgen excess. 17-OHP = 17-hydroxyprogesterone; ACTH = adrenocorticotropin hormone; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; PCOS = polycystic ovarian syndrome; T = testosterone; TFTs = thyroid function tests.

17-Alpha Hydroxyprogesterone

The term congenital adrenal hyperplasia (CAH) describes several autosomal recessive disorders that result from complete or partial deficiency of an enzyme involved in cortisol and aldosterone synthesis, usually 21-hydroxylase or less frequently 11-hydroxylase (Fig. 16-5, p. 339). As a result of these defects, precursors are shunted into pathways leading to androgen production. Thus, depending on the enzyme affected, CAH symptoms vary. It may present in the neonate with ambiguous genitalia and life-threatening hypotension (Chap. 19, p. 415).

FIGURE 18-9 Woman with virilization manifest by clitoromegaly. (From Kiszka, 2019, with permission.)

Alternatively, symptoms may be milder and delayed until adolescence or adulthood. In this late-onset form of CAH, the enzyme deficiency leads to a relative cortisol deficiency. In response, adrenocorticotropic hormone (ACTH) levels rise to normalize cortisol production. Consequent to this accommodation, adrenal gland hyperplasia and elevated androgen levels develop. Therefore, symptoms of late-onset CAH reflect accumulation of precursor C_{19} steroid hormones. These precursors are converted to dehydroepiandrosterone, androstenedione, and testosterone. Thus, signs of hyperandrogenism predominate.

With late-onset CAH, the most commonly affected enzyme is 21-hydroxylase, and deficiency leads to accumulation of its substrate, 17-hydroxyprogesterone. Serum values are drawn in the morning from a fasting patient. Threshold values of 17-hydroxyprogesterone that measure >200 ng/dL should prompt an ACTH stimulation test. With this test, synthetic ACTH, 250 µg, is injected intravenously, and a serum 17-hydroxyprogesterone level is measured 1 hour later.

To explain this test, the ACTH given during testing stimulates uptake of cholesterol and synthesis of pregnenolone. If 21-hydroxylase activity is ineffective, steroid precursors up to and including progesterone, 17-hydroxypregnenolone, and especially 17-hydroxyprogesterone accumulate in the adrenal cortex and in circulating blood. In affected individuals, serum levels of 17-hydroxyprogesterone can reach many times their normal concentrations. Levels >1000 ng/dL from blood drawn after synthetic ACTH is given are indicative of late-onset CAH.

Antimüllerian Hormone

The classic polycystic ovary contains two- to threefold more growing preantral and antral follicles than normal ovaries (Hughesdon, 1982). Within the granulosa cells of these developing follicles, the dimeric glycoprotein antimüllerian hormone (AMH) is produced. Serum AMH levels correlate closely with the number of preantral and antral follicles. Not surprisingly, AMH levels are two- to threefold higher in women with PCOS compared with nonaffected age-matched controls (Cui, 2014: Homburg, 2013). For this reason, some view AMH as a potentially useful diagnostic marker for PCOS (Iliodromiti, 2013; Pigny, 2006). That said, data regarding this marker in both PCOS and controls are incomplete and require further investigation before it can be adopted as a formal diagnostic criterion (Dewailly, 2014a; Teede, 2019).

Cortisol

Cushing syndrome results from prolonged exposure to elevated levels of either endogenous or exogenous glucocorticoids. Of these, the syndrome is most frequently caused by administration of exogenous glucocorticoids. Alternatively, the term *Cushing disease* is reserved for cases stemming from greater ACTH secretion by a pituitary tumor. Cushing syndrome shares many symptoms with PCOS such as menstrual dysfunction, physical signs of androgen excess, truncal obesity, dyslipidemia, and glucose intolerance. Classically, moon facies and purple abdominal striae also are noted. Excluding exogenous causes, Cushing syndrome is rare, and routine screening in all women with oligomenorrhea is not indicated. However, in those with classic Cushing findings, proximal muscle weakness, and easy bruising, screening is strongly considered (Nieman, 2008).

Initial laboratory testing investigates excessive glucocorticoid production, and three are endorsed by the Endocrine Society (Nieman, 2008). Of these, a 24-hour urine collection for urinary free cortisol excretion can be obtained. Alternatively, a dexamethasone suppression test administers 1 mg of dexamethasone orally at 11 PM, and a plasma cortisol level is measured at 8 AM the following morning. In women with a normal functioning feedback loop, administration of the corticosteroid dexamethasone lowers ACTH secretion and thus diminishes adrenal cortisol production. Normal testing values are <5 µg/dL (Crapo, 1979). However, if a woman has an exogenous or an ectopic endogenous source of cortisol, then cortisol levels during suppression testing will remain elevated. Last, using a late-night salivary cortisol level measurement, patients collect saliva samples between 11 PM and midnight on two separate evenings. Once identified, Cushing syndrome is treated based on the underlying source of excess glucocorticosteroid.

Measurements of Insulin Resistance and Dyslipidemia

Many women with PCOS have insulin resistance and compensatory hyperinsulinemia. The "gold standard" for evaluating insulin resistance has been the hyperinsulinemic euglycemic clamp. Unfortunately, this test and the intravenous glucose tolerance test (IV GTT) require an intravenous line and frequent sampling, are labor and time intensive, and are not practical in a clinical setting. Accordingly, other less sensitive surrogate markers that evaluate insulin resistance are used. These include: (1) a 2-hour oral glucose tolerance test (2-hr OGTT), (2) a fasting serum insulin level, (3) the homeostasis model assessment of insulin resistance (HOMA IR), (4) the quantitative insulin sensitivity check (QUICKI), and (5) calculation of serum glucose:insulin ratios.

Several organizations recommend initial DM screening and then periodic testing in obese or overweight women and adolescents diagnosed with PCOS (American Diabetes Association, 2019; Goodman, 2015; Witchel, 2015). Normal and abnormal testing level thresholds are found in Table 1-15 (p. 18). Guidelines endorsed by ESHRE and ASRM promote baseline DM screening for *all* women with PCOS and subsequent testing at 1- to 3-year intervals based on risks. Serum fasting glucose level, hemoglobin A_{1C} (HbA_{1C}) level, or 2-hr OGTT is suitable. Of these, 2-hr OGTT is favored for higher-risk characteristics, which are obesity (BMI >25 kg/m^2 or >23 in Asian women), a personal history of IGT or hypertension, Asian ethnicity, and family history of type 2 DM (Teede, 2019). Women with PCOS can demonstrate a worsening of glucose tolerance over time, with a reported conversion rate of approximately 2 percent per year to type 2 DM. This affirms the importance of periodic assessment of glucose tolerance with a 2-hr OGTT in women with PCOS (Legro, 1999, 2005).

In addition to assessment of insulin resistance, in overweight and obese women with PCOS, a fasting lipid profile is recommended to evaluate dyslipidemia (Teede, 2019). Subsequent testing is based on global CVD risk. Others support initial lipid screening for *all* women with PCOS (American College of Obstetricians and Gynecologists, 2018; Wild, 2011). Evaluation and treatment of dyslipidemia are further described in Chapter 1 (p. 17).

Sonography

Histologically, a polycystic ovary displays a greater number of ripening and atretic follicles, cortical stromal thickness, and number of hilar cell nests (Hughesdon, 1982). Many of these tissue changes can be seen sonographically, and pelvic sonography is commonly used to evaluate the ovaries in women with suspected PCOS. Moreover, sonography is particularly important for women with PCOS seeking fertility and in women with signs of virilization to exclude an androgen-producing ovarian cancer.

FIGURE 18-10 Transvaginal sonography displays multiple small hypoechoic cysts. (Reproduced with permission from Dr. Elysia Moschos.)

Polycystic ovarian morphology (PCOM) is one criterion for PCOS diagnosis (see Table 18-1). Earlier sonographic criteria for PCOM included ≥12 small cysts (2 to 9 mm in diameter) or an increased ovarian volume (>10 mL) or both per ovary (Fig. 18-10). More recently, follicle number per ovary (FNPO) threshold values have been raised due to improved sonographic imaging resolution (Dewailly, 2011; Lujan, 2013). Namely, an FNPO threshold of >20 follicles and/or ovarian volume >10 mL in either ovary has been adopted by ESHRE and ASRM. The AE-PCOS guidelines use the same ovarian volume value but a higher FNPO threshold of ≥25 follicles (Dewailly, 2014b). Notably, criteria do not apply to women taking combination oral contraceptive pills.

Remarkably, studies using sonography have shown that at least 23 percent of young women have ovaries that exhibit PCOM, yet many of these women have no other PCOS symptoms (Clayton, 1992; Polson, 1988). In addition, a polycystic appearance of the ovaries can often be found in other conditions of androgen excess, such as CAH, Cushing syndrome, and exogenous use of androgenic medications. For this reason, PCOM found during sonographic examination is not used solely for PCOS diagnosis.

Importantly, PCOM often reflects normal adolescent ovarian physiology (Hickey, 2011; Kristensen, 2010). Thus, sonography for PCOS evaluation is not recommended within 8 years of menarche (Teede, 2019).

TREATMENT

The treatment choice for each symptom of PCOS depends on a woman's goals and the severity of endocrine dysfunction. Thus, anovulatory women desiring pregnancy will undergo significantly different treatment than adolescents with menstrual irregularity and acne. Patients often seek treatment for a singular complaint and may see various specialists such as dermatologists, nutritionists, aestheticians, and endocrinologists prior to evaluation by a gynecologist.

Conservative Treatment

Women with PCOS who have fairly regular cycle intervals (8 to 12 menses per year) and mild hyperandrogenism may choose not to be treated. In these women, however, periodic screening for dyslipidemia, DM, and metabolic syndrome is reasonable.

For obese women with PCOS, important lifestyle changes focus on diet and exercise. Even modest weight loss (5 percent of body weight) can result in restoration of normal ovulatory cycles in some women. This improvement results from reductions in insulin and androgen levels, the latter mediated through increases in SHBG levels (Huber-Buchholz, 1999; Kiddy, 1992; Pasquali, 1989). Weight loss strategies are described in Chapter 1 (p. 14). Diet is one important element, and a well-balanced hypocaloric diet offers the most benefit in treating obese women with PCOS. Exercise improves weight, blood pressure, and fasting insulin and lipid levels in women with PCOS (Benham, 2018; Harrison, 2011; Jaatinen, 1993; Kite, 2019). Similarly in affected women, exercise improves cardiovascular capacity (Haqq, 2015; Vigorito, 2007).

Treatment of Oligo- and Anovulation

Hormonal Agents

Women with oligo- or anovulation typically have fewer than nine menses per year, often skip menses for several months at a time, or simply have amenorrhea. Flow may be scanty or may be prolonged and heavy, resulting in iron-deficiency anemia.

A first-line treatment for menstrual irregularities is combination oral contraceptive pills (COCs), which induce regular menstrual cycles, lower androgen levels, and thin the endometrium. Specifically, COCs suppress gonadotropin release, which results in decreased ovarian androgen production. Moreover, the estrogen component raises levels of SHBG, which binds free androgen. Last, the progestin component antagonizes the endometrial proliferative effect of unopposed estrogen from PCOS, thus reducing the endometrial hyperplasia risk.

Theoretically, COCs that contain progestins with fewer androgenic properties are preferred. However, no COC pill has shown superiority compared with another in reducing hirsutism (Sobbrio, 1990). Alternative combination hormonal contraceptive options include the contraceptive patch and vaginal ring.

In patients who are not candidates for combination hormonal contraception, progesterone withdrawal is recommended every 1 to 3 months. Examples of regimens used include: medroxyprogesterone acetate (MPA), 5 to 10 mg orally daily day for 12 days, or micronized progesterone, 200 mg orally each evening for 12 days. Patients are counseled that intermittent progestins will not reduce symptoms of acne or hirsutism, nor do they provide contraception. For those requiring birth control, a continuous progestin-only contraceptive pill, depot medroxyprogesterone acetate, or a progestin-releasing implant or intrauterine device may be used and will act to thin the endometrium.

Insulin Sensitizers

Metformin is a biguanide insulin sensitizer agent that is Food and Drug Administration (FDA) approved for glycemic control in type 2 DM. It is often used off-label for patients with PCOS

to help restore cyclic menses, lower hyperandrogenism, and aid weight loss.

Importantly, for obese women with PCOS, weight loss and exercise are first-line strategies to reduce many of the short- and long-term side effects of PCOS, such as infertility, CVD, and DM. Thus, metformin is typically reserved for patients with PCOS and with IGT, elevated fasting insulin levels, and acanthosis nigricans. Some patients with a strong family history of DM also will benefit from metformin.

Side effects may include bloating, nausea, and diarrhea. Lactic acidosis is rare and typically develops in patients with impaired renal function. An initial 500-mg, extended-release form taken orally once daily with a meal can offset gastrointestinal side effects. This dose then can be increased slowly every 1 to 2 weeks to a final 1500-mg or 2000-mg daily dose, which can be divided across meals.

For anovulatory infertility, ESRE/ASRM guidelines recommend first-line treatment with letrozole or clomiphene citrate in women with PCOS (American Society for Reproductive Medicine, 2017; Teede, 2019). Metformin is a second-line agent. The addition of metformin to clomiphene citrate may be indicated for women with the constellation of PCOS, clomiphene citrate resistance, and anovulatory infertility. Metformin is a pregnancy category B drug.

The thiazolidinediones are another class of medications used in patients with DM. However, because of their potential for serious side effects and weight gain and their pregnancy category C status, this group is discouraged for PCOS.

Agonists of the glucagon-like peptide 1 (GLP-1) receptor make up another class of medications used for type 2 DM. One metaanalysis comparing GLP-1 agonists against metformin in women with PCOS found greater weight loss and insulin sensitivity in the GLP-1 agonist group (Han, 2019). This class is not recommended in pregnancy and should not be used in patients at risk for conceiving.

Another class of medications for patients with type 2 DM is the sodium-glucose cotransporter 2 (SGLT2) inhibitors. In patients with DM, weight loss and CVD risk factors benefit. In women with PCOS, weight loss with the SGLT2 empagliflozin was superior to that with metformin (Javed, 2019). It is pregnancy category C and not recommended in those at risk for pregnancy.

Hirsutism

With hirsutism treatment, a primary goal is lowering androgen levels to halt further conversion of vellus hairs to terminal ones. First, as described earlier, COCs are effective in establishing regular menses and lowering ovarian androgen production (p. 400). These are a first-line option in women who are candidates for COCs. However, medical therapies will not eliminate hair already present. Moreover, treatments may require 6 to 12 months before clinical improvement is apparent. For this reason, clinicians should be familiar with temporary hair removal methods that may be used in the interim.

Hair Removal

Both depilation and epilation are suitable techniques. In addition to hair removal, lightening hair color with bleach is a cosmetic option.

Depilation describes hair removal above the skin surface. Shaving is the most common form and does not exacerbate hirsutism, contrary to the myth that it will increase hair follicle density. Alternatively, topical chemical depilatories also are effective. Available in gel, cream, lotion, aerosol, and roll-on forms, these agents contain calcium thioglycolate. This agent breaks disulfide bonds between hair protein chains, causing hair to break down and separate easily from the skin surface.

Epilation removes the entire hair shaft and root and includes techniques such as plucking, waxing, threading, electrolysis, and laser treatment. Threading, also known as *khite* in Arabic, is a fast method for removing entire hairs and is commonly used in the Middle East and India. Hairs are snared within an outstretched strand of twisted cotton thread and pulled out.

Although waxing and plucking allow effective temporary hair removal, permanent epilation may be achieved with thermal destruction of the hair follicle. Electrolysis, performed by a trained individual, involves placement of a fine electrode and passage of electric current to destroy individual follicles. It requires repetitive treatments over several weeks to months, can be painful, and can result in scarring.

Alternatively, laser therapy directs specific laser wavelengths to permanently destroy follicles. During this process, termed *selective photothermolysis*, only target tissues absorb laser light and are heated. Surrounding tissues fail to absorb the selective wavelength and receive minimal thermal damage. For this reason, light-skinned women with dark hairs are better candidates for laser treatment due to the selective wavelength absorption by their hair. Advantageously, laser treatment can cover a wider surface area than electrolysis and therefore requires fewer treatments. It causes less pain, but is expensive and can result in dyspigmentation.

Prior to any epilation technique, topical anesthetics may be prescribed. Specifically, a topical cream combination of 2.5-percent lidocaine and 2.5-percent prilocaine (EMLA cream) can be applied as a thick layer that remains for 5 to 10 minutes and is removed just prior to epilation. Recommended adult dosing is 2.5 g for each 2 × 2-inch area of skin treated.

Eflornithine Hydrochloride

This antimetabolite topical cream is applied twice daily to affected areas and is an irreversible inhibitor of ornithine decarboxylase. This enzyme is necessary for hair follicle cell division and function, and its inhibition results in slower hair growth. Consequently, it does not permanently remove hair, and women must continue routine methods of hair removal while using this medicine.

Eflornithine hydrochloride (Vaniqa) is FDA-approved for treatment of female facial hirsutism. It may require 4 to 8 weeks of use before changes are noticed. However, approximately one third of patients have marked improvement after 24 weeks of eflornithine use compared with placebo, and 58 percent showed some overall improvement in hirsutism scores by this time (Wolf, 2007). Local burning and erythema are potential side effects.

Spironolactone

Although not FDA-approved for this indication, spironolactone (Aldactone) is the primary antiandrogen used currently in the United States for hirsutism. It is a competitive inhibitor

of androgen binding to the androgen receptor. This drug also directly inhibits 5α-reductase. The typical dosage is 50 to 100 mg orally twice daily.

Spironolactone effectively treats hirsutism but carries important risks (Brown, 2009; Moghetti, 2000; Venturoli, 1999). First, as an antiandrogen, it bears a theoretical risk of interfering with external genitalia development in male fetuses of women using such medications in early pregnancy. Accordingly, it is commonly used in conjunction with COCs. Second, if used as monotherapy, intermenstrual bleeding frequently develops. Last, spironolactone is also a potassium-sparing diuretic. As such, it is not prescribed for chronic use in combination with agents that can also raise blood potassium levels, such as potassium supplements, angiotensin-converting enzyme inhibitors, nonsteroidal antiinflammatory drugs such as indomethacin, or other potassium-sparing diuretics.

Flutamide is another antiandrogen marketed for the treatment of prostate cancer. It is uncommonly used for hirsutism due to its potential hepatotoxicity. As an antiandrogen, teratogenicity again is a concern.

Finasteride

This agent is a 5α-reductase inhibitor, which blocks conversion of testosterone to DHT. Most studies have used 5-mg daily doses for women and have found finasteride to be modestly effective for hirsutism treatment (Fruzzetti, 1994; Moghetti, 1994). Side effects are few, although decreased libido has been noted. As with other antiandrogens, the risk of male fetal teratogenicity is present, and effective contraception must be used concurrently.

Acne

One part of acne treatment is similar to that for hirsutism and involves lowering of androgen levels. As such, therapy may include COC pills or spironolactone. In addition or alternatively, the subsequent therapies may be used.

In general, mild acne may be treated with benzoyl peroxide or topical retinoid monotherapy. If needed, benzoyl peroxide can be combined with a topical retinoid or with topical antimicrobial therapy. Moderate to severe acne may require triple therapy with the above agents. Oral retinoids or oral antibiotics are other options (Zaenglein, 2016). For this reason, women with moderate to severe acne may benefit from consultation with a dermatologist.

Topical benzoyl peroxide is bactericidal to *P acnes* by generating reactive oxygen species within the follicle. It also has weak comedolytic and antiinflammatory properties. It is the active ingredient in many over-the-counter acne products, but some prescription preparations also combine benzoyl peroxide with topical clindamycin or erythromycin.

Topical retinoids regulate the follicular keratinocyte and normalize its desquamation. In addition, these agents also have direct antiinflammatory properties and thereby target two factors linked to acne vulgaris. The most commonly used of these is tretinoin. Adapalene and tazarotene also are effective (Gold, 2006; Leyden, 2006). Initially, a pea-sized dab sufficient to cover the entire face is applied every third night and progressively increased as tolerated to nightly application. Tretinoin may cause a transient worsening of acne during the first weeks of treatment.

Tretinoin and adapalene are category C drugs and thus are not recommended for use during pregnancy or breastfeeding. However, epidemiologic studies currently do not support a link between topical retinoids and birth defects (Jick, 1993; Loureiro, 2005). Tazarotene is category X and similarly is not used during these times. It requires highly effective contraception.

Topical antibiotics typically are erythromycin and clindamycin, whereas oral antibiotics most often used for acne include doxycycline, minocycline, and erythromycin. Oral antibiotics are more effective than topical therapies but can have various side effects such as sun sensitivity and gastrointestinal upset.

Oral isotretinoin (Accutane) successfully treats severe recalcitrant acne. Despite its efficacy, oral isotretinoin is teratogenic if taken during the first trimester of pregnancy. Malformations typically involve the cranium, face, heart, central nervous system, and thymus. Therefore, isotretinoin administration is limited to women using highly effective contraception.

Surgical Therapy

Although ovarian wedge resection is now rarely performed, laparoscopic ovarian drilling restores ovulation in many women with PCOS that is resistant to clomiphene citrate (Section 44-7, p. 1036) (Farquhar, 2012). Rarely, GnRH agonists or oophorectomy is a viable option for women not seeking fertility who exhibit signs and symptoms of ovarian hyperthecosis and accompanying severe hyperandrogenism.

Congenital anatomic disorders of the female reproductive tract develop frequently and result from insults at critical embryonic stages. Influences include genetic mutation, epigenetic factors, developmental arrest, or abnormal hormonal exposures. Disorders range from congenital absence of the vagina and uterus, to lateral or vertical fusion defects of the müllerian ducts, to external genitalia that are ambiguous. Sexual differentiation is complex and requires both hormonal pathways and morphologic development to be normal and correctly integrated. Thus, neonates with genital anomalies not surprisingly often have multiple other malformations. Associated urinary tract defects are especially frequent and are linked to the concurrent embryonic development of both reproductive and urinary tracts (Hutson, 2014).

NORMAL EMBRYOLOGY

The urogenital tract is functionally divided into the urinary system and genital system. The urinary organs include the kidney, ureters, bladder, and urethra. The reproductive organs are the gonads, ductal system, and external genitalia. Like most organ systems, the female urogenital tract develops from multiple cell types that undergo important spatial growth and differentiation. These develop during relatively narrow time windows and are governed by time-linked patterns of gene expression (Park, 2005).

Both the urinary and genital systems develop from intermediate mesoderm, which extends along the entire embryo length. During initial embryo folding, a longitudinal ridge of this intermediate mesoderm develops along each side of the primitive abdominal aorta and is called the *urogenital ridge*. Subsequently, the urogenital ridge divides into the *nephrogenic ridge* and the *genital ridge*, also called the *gonadal ridge* (Fig. 19-1).

At approximately 60 days of gestation, the nephrogenic ridges develop into the *mesonephric kidneys* and paired *mesonephric ducts*, also termed *wolffian ducts*. These mesonephric ducts connect the mesonephric kidneys (destined for resorption) to the *cloaca*, which is a common opening into which the embryonic urinary, genital, and alimentary tracts join (Fig. 19-2A). Recall that evolution of the renal system passes sequentially through the pronephric and mesonephric stages to reach the permanent metanephric system. The ureteric bud arises from the mesonephric duct at approximately the fifth week of fetal life. It lengthens to become the metanephric duct (ureter) and induces differentiation of the metanephros, which will eventually become the final functional kidney.

The paired *paramesonephric ducts*, also termed the *müllerian ducts*, develop from invagination of the coelomic epithelium at approximately the sixth week and grow alongside the mesonephric ducts (Figs. 19-1B and 19-2B). The caudal portions of the müllerian ducts approximate one another in the midline and end behind the cloaca (Fig. 19-2C). The cloaca is divided by formation of the urorectal septum by the seventh week and is separated to create the *rectum* and the *urogenital sinus* (Fig. 19-1D). The urogenital sinus is considered in three parts: (1) the cephalad or vesicle portion, which will form the urinary bladder; (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which will give rise to the distal vagina and the greater vestibular (Bartholin) glands and paraurethral glands. During differentiation of the urinary bladder, the caudal portion of the mesonephric ducts is incorporated into the trigone of the bladder wall. Consequently, the caudal portion of the metanephric ducts (ureters) penetrates the bladder with distinct and separate orifices (see Fig. 19-2D).

The close association between the mesonephric (wolffian) and paramesonephric (müllerian) ducts has important clinical relevance because developmental insult to either system is often associated with anomalies that involve the kidney, ureter, and reproductive tract. For example, Kenney and colleagues (1984) noted that up to 50 percent of females with uterovaginal malformations have associated urinary tract anomalies.

Gonadal Determination

Mammalian sex is determined genetically. Individuals with X and Y chromosomes usually develop as males, whereas those

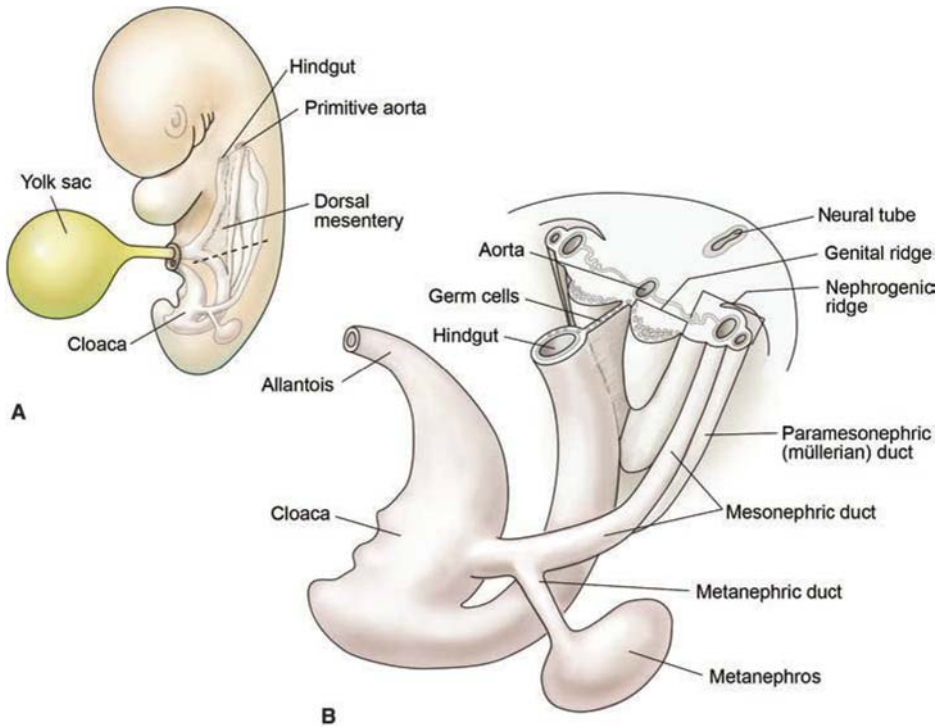

FIGURE 19-1 Early development of the embryonic genitourinary tract. **A.** In the developing embryo, the urogenital ridge forms from coelomic mesenchyme lateral to the primitive aorta. **B.** Cross section through the embryo shows division of the urogenital ridges into the genital ridge (future gonad) and nephrogenic ridge, which contains the mesonephros and mesonephric (wolffian) ducts. The mesonephros is the primitive kidney and is connected by the mesonephric ducts to the cloaca. Primordial germ cells migrate along the dorsal mesentery of the hindgut to reach the genital ridge. Paramesonephric (müllerian) ducts develop lateral to the mesonephric ducts. (Reproduced with permission from Kim Hoggatt-Krumwiede, MA.)

TABLE 19-1. Embryonic Urogenital Structures and Their Adult Homologues

Indifferent Structure	Female	Male
Genital ridge	Ovary	Testis
Primordial germ cells	Ova	Spermatozoa
Sex cords	Granulosa cells	Seminiferous tubules, Sertoli cells
Gubernaculum	Uteroovarian and round ligaments	Gubernaculum testis
Mesonephric tubules	Epoophoron, paroophoron	Efferent ductules, paradidymis
Mesonephric ducts	Gartner duct	Epididymis, ductus deferens, ejaculatory duct
Paramesonephric ducts	Uterus, fallopian tubes, upper vagina	Prostatic utricle, appendix of testis
Urogenital sinus	Bladder, urethra Vagina Paraurethral glands Greater (Bartholin) and lesser vestibular glands	Bladder, urethra Prostatic utricle Prostate glands Bulbourethral glands
Genital tubercle	Clitoris	Glans penis
Urogenital folds	Labia minora	Floor of penile urethra
Labioscrotal swellings	Labia majora	Scrotum

with two X chromosomes develop as females. Before 7 weeks of embryonic development, embryos of male and female sex are indistinguishable from one another (Table 19-1).

During this indeterminate time, the genital ridge begins as coelomic epithelium with underlying mesenchyme. The epithelium proliferates, and cords of epithelium invaginate into the mesenchyme to create primitive sex cords. In both 46,XX and 46,XY embryos, the primordial germ cells are first identified as large polyhedral cells in the yolk sac. These germ cells migrate by amoeboid motion along the hindgut dorsal mesentery to populate the undifferentiated genital ridge (see Fig. 19-1). Thus, the major cellular components of the early genital ridge include primordial germ cells and somatic cells.

At this point, gonadal determinant genes direct fetal gender development (Fig. 19-3) (Taylor, 2000). *Sexual determination* is the development of the genital ridge into either an ovary or testis. This depends on the genetic sex produced at fertilization, when the X-bearing oocyte is penetrated by either an X- or Y-chromosome-bearing sperm. In humans, the gene named the *sex-determining region of the Y (SRY)* is the testis-determining factor. In the presence of *SRY*, gonads typically develop as testes. Other genes are important for normal gonad development and include *SOX9*, *SF-1*, *DMRT1*, *GATA4*, *WNT4*, *WT1*, *DAX1*, and *RSPO1* (Arboleda, 2014; Blaschko, 2012). Not surprisingly, mutations in any of these genes may lead to abnormal sexual determination. Moreover, gene dosage and relative expression levels play an important role (Ocal, 2011).

In males, cells in the medullary region of the primitive sex cords differentiate into Sertoli cells, and these cells organize to form the testicular cords (Fig. 19-3A). Testicular cords are identifiable at 6 weeks and consist of these Sertoli cells and tightly packed germ cells. Early in the second trimester, the cords develop a lumen and become seminiferous tubules. Development of a testis-specific vasculature is crucial for normal testicular development (Ross, 2005).

During this early development, Sertoli cells begin secreting *antimüllerian hormone (AMH)*, also called *müllerian inhibitory substance (MIS)*. This gonadal hormone causes regression of the ipsilateral paramesonephric (müllerian duct) system, and this involution is completed by 9 to 10 weeks' gestation (Marshall, 1978). AMH also controls the rapid gubernacular growth necessary for the transabdominal descent of the testis. Serum AMH levels remain elevated in boys during childhood and then decline at puberty to the low levels seen in adult men.

In the testes, Leydig cells arise from the original mesenchyme of the genital ridge and lie between the testicular cords. The Leydig cells begin to secrete testosterone by 8 weeks' gestation due to stimulation of the testes by human chorionic gonadotropin (hCG). Testosterone acts in a paracrine manner on the ipsilateral mesonephric (wolffian) duct to promote virilization of the duct into the epididymis, vas deferens, and seminal vesicle. In addition, the androgens testosterone and dihydrotestosterone (DHT) are essential for male phenotype development. These androgens control differentiation and growth of the internal ducts and external genitalia and also prime male differentiation of the brain.

In the female embryo, without the influence of the *SRY* gene, the bipotential gonad develops into the ovary. The pathways regulating female sex determination have remained incompletely defined, but *WNT4*, *WT1*, *FoxL2*, and *DAX1* genes are important for normal development (Arboleda, 2014; MacLaughlin, 2004). Compared with testicular development, ovarian determination is delayed by approximately 2 weeks. Development is first characterized by the absence of testicular cords in the gonad. The primitive sex cords degenerate, and the mesothelium of the genital ridge forms secondary sex cords (Fig. 19-3B). These secondary cords become the granulosa cells that band together to form the follicular structures that surround the germ cells. Oocytes and the surrounding granulosa cells begin communication when the resting primordial

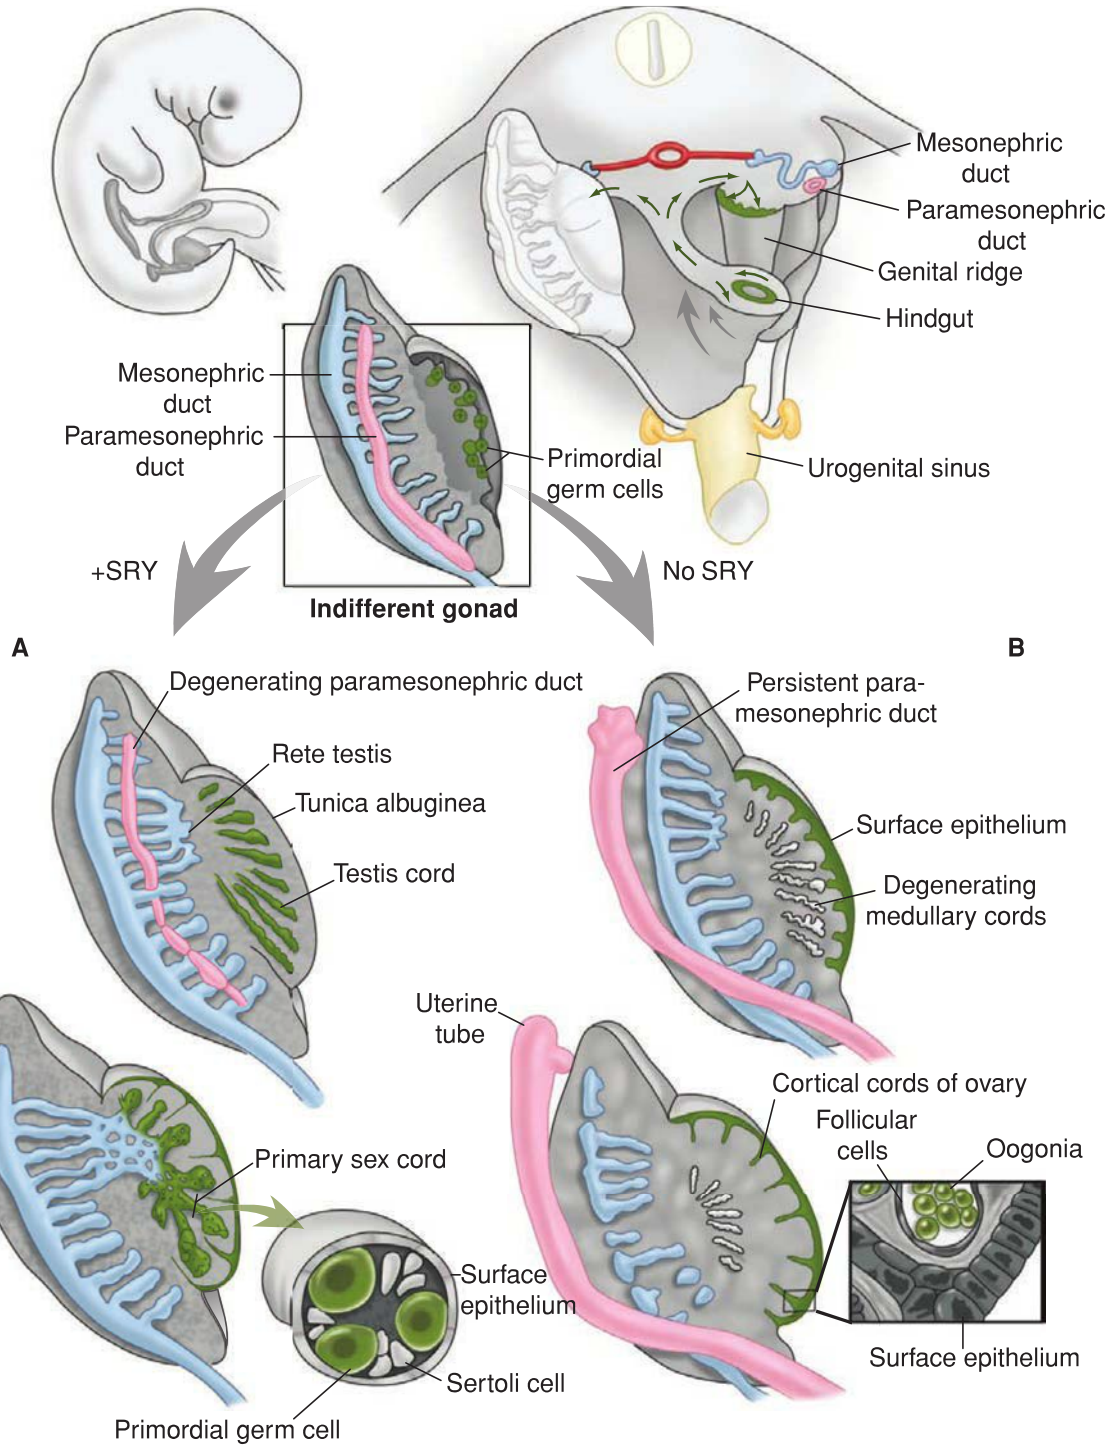

FIGURE 19-3 Development of the gonads and ductal systems in male **(A)** and female **(B)** embryos. SRY = sex-determining region of the Y. (Reproduced with permission from Hoffman, 2018.)

follicles are stimulated to grow under the influence of follicle-stimulating hormone (FSH) at puberty. The medullary portion of the gonad regresses and forms the rete ovarii within the ovarian hilum.

Germ cells that carry two X chromosomes undergo mitosis during their initial migration to the female genital ridge. They reach a peak number of 5 to 7 million by 20 weeks' gestation. At this time, the fetal ovary demonstrates mature organization of stroma and primordial follicles containing oocytes. During the third trimester, oocytes begin meiosis but arrest during meiosis I until the oocyte undergoes ovulation after menarche. Atresia of the oocytes starts in utero, leading to a reduced number of germ cells at birth (Fig. 15-1, p. 321).

Ductal System Development

Sexual differentiation of the mesonephric (wolffian) and paramesonephric (müllerian) ducts begins in week 7 from the

influence of gonadal hormones (testosterone and AMH) and other factors. In the male, AMH forces paramesonephric regression, and testosterone prompts mesonephric duct differentiation into the epididymis, vas deferens, and seminal vesicles.

In the female, a lack of AMH allows müllerian ducts to persist. Early, these ducts grow caudally along with the mesonephric ducts. During paramesonephric duct elongation, homeobox (Hox) genes in groups 9–13 play a role in determining positional identity along the long axis of the developing duct. For example, *HoxA9* is one such gene that is expressed at high levels in areas destined to become the fallopian tube (Park, 2005). *HoxA10* and *HoxA11* are expressed in the developing uterus and in the adult uterus. These and other ovarian determinant genes play an active role in gonadal and reproductive tract morphogenesis, but mechanisms are yet to be elucidated fully (Massé, 2009; Taylor, 2000).

During their elongation, both mesonephric and paramesonephric duct systems become enclosed in peritoneal folds that later give rise to the broad ligaments of the uterus. At approximately 10 weeks' gestation and during their caudal migration, the two distal portions of the müllerian ducts approach each other in the midline and fuse even before they reach the urogenital sinus. The fused ducts form a tube called the *uterovaginal canal*. This tube then inserts into the urogenital sinus at the Müller tubercle (Fig. 19-2E).

By 12 weeks, mesonephric ducts regress from lack of testosterone. The uterine corpus and cervix differentiate, and the uterine wall thickens. Initially, the upper pole of the uterus contains a thick midline septum that undergoes dissolution to create the uterine cavity. Dissolution of the uterine septum is usually completed by 20 weeks' gestation. The unfused cephalad portions of the müllerian ducts become the fallopian tubes (Fig. 19-2F). Any failure of lateral fusion of the two müllerian ducts or failure to reabsorb the septum between them results in separate uterine horns or some degree of persistent midline uterine septum.

Most investigators suggest that the vagina develops under influence from the müllerian ducts and estrogenic stimulation. The vagina forms partly from the müllerian ducts and partly from the urogenital sinus (Massé, 2009). Specifically, the upper two thirds of the vagina derive from the fused müllerian ducts. The distal third of the vagina develops from the bilateral *sinovaginal bulbs*, which are cranial evaginations of the urogenital sinus.

During vaginal development, the müllerian ducts reach the urogenital sinus at the Müller tubercle (Fig. 19-4A). Here, cells in the sinovaginal bulbs proliferate cranially to lengthen the vagina and create a solid vaginal plate (Fig. 19-4B). During the second trimester, these cells desquamate, allowing full canalization of the vaginal lumen (Fig. 19-4C). The hymen is the partition that remains to a varying degree between the dilated, canalized, fused sinovaginal bulbs and the urogenital sinus (see Fig. 19-4B,C). The hymen usually perforates shortly before or after birth. An imperforate hymen represents persistence of this membrane.

External Genitalia

Early development of the external genitalia is similar in both sexes. By 6 weeks' gestation, three external protuberances have developed surrounding the cloacal membrane. These are the left and right cloacal folds, which meet ventrally to form the genital tubercle (Fig. 19-5A). With division of the cloacal membrane into anal and urogenital membranes, the cloacal folds become

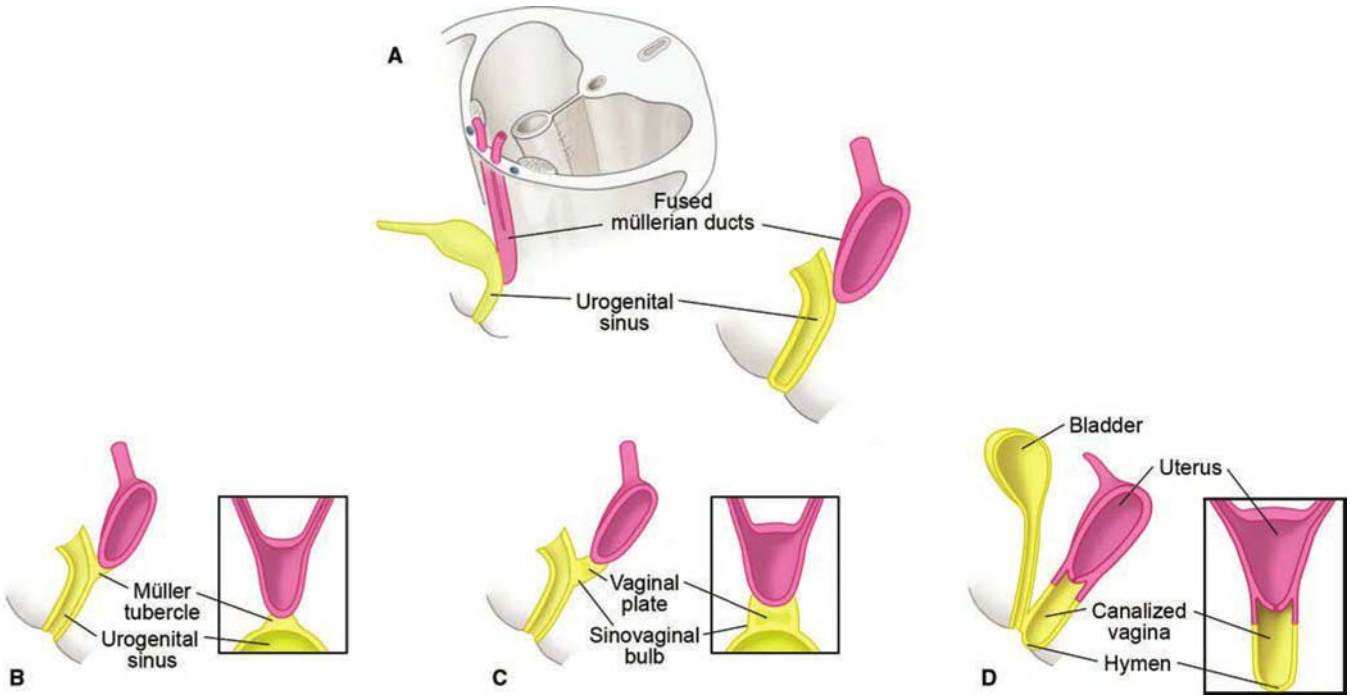

FIGURE 19-4 Development of the lower female reproductive tract. **A.** The fused müllerian ducts join the urogenital sinus at the Müller tubercle. **B.** From the urogenital sinus, the sinovaginal bulbs evaginate and proliferate cranially to create the vaginal plate **(C)**. **D.** Lengthening of the vaginal plate and canalization leads to development of the lower vagina. The upper vagina develops from the caudal end of the fused müllerian ducts. (Reproduced with permission from Kim Hoggatt-Krumwiede, MA.)

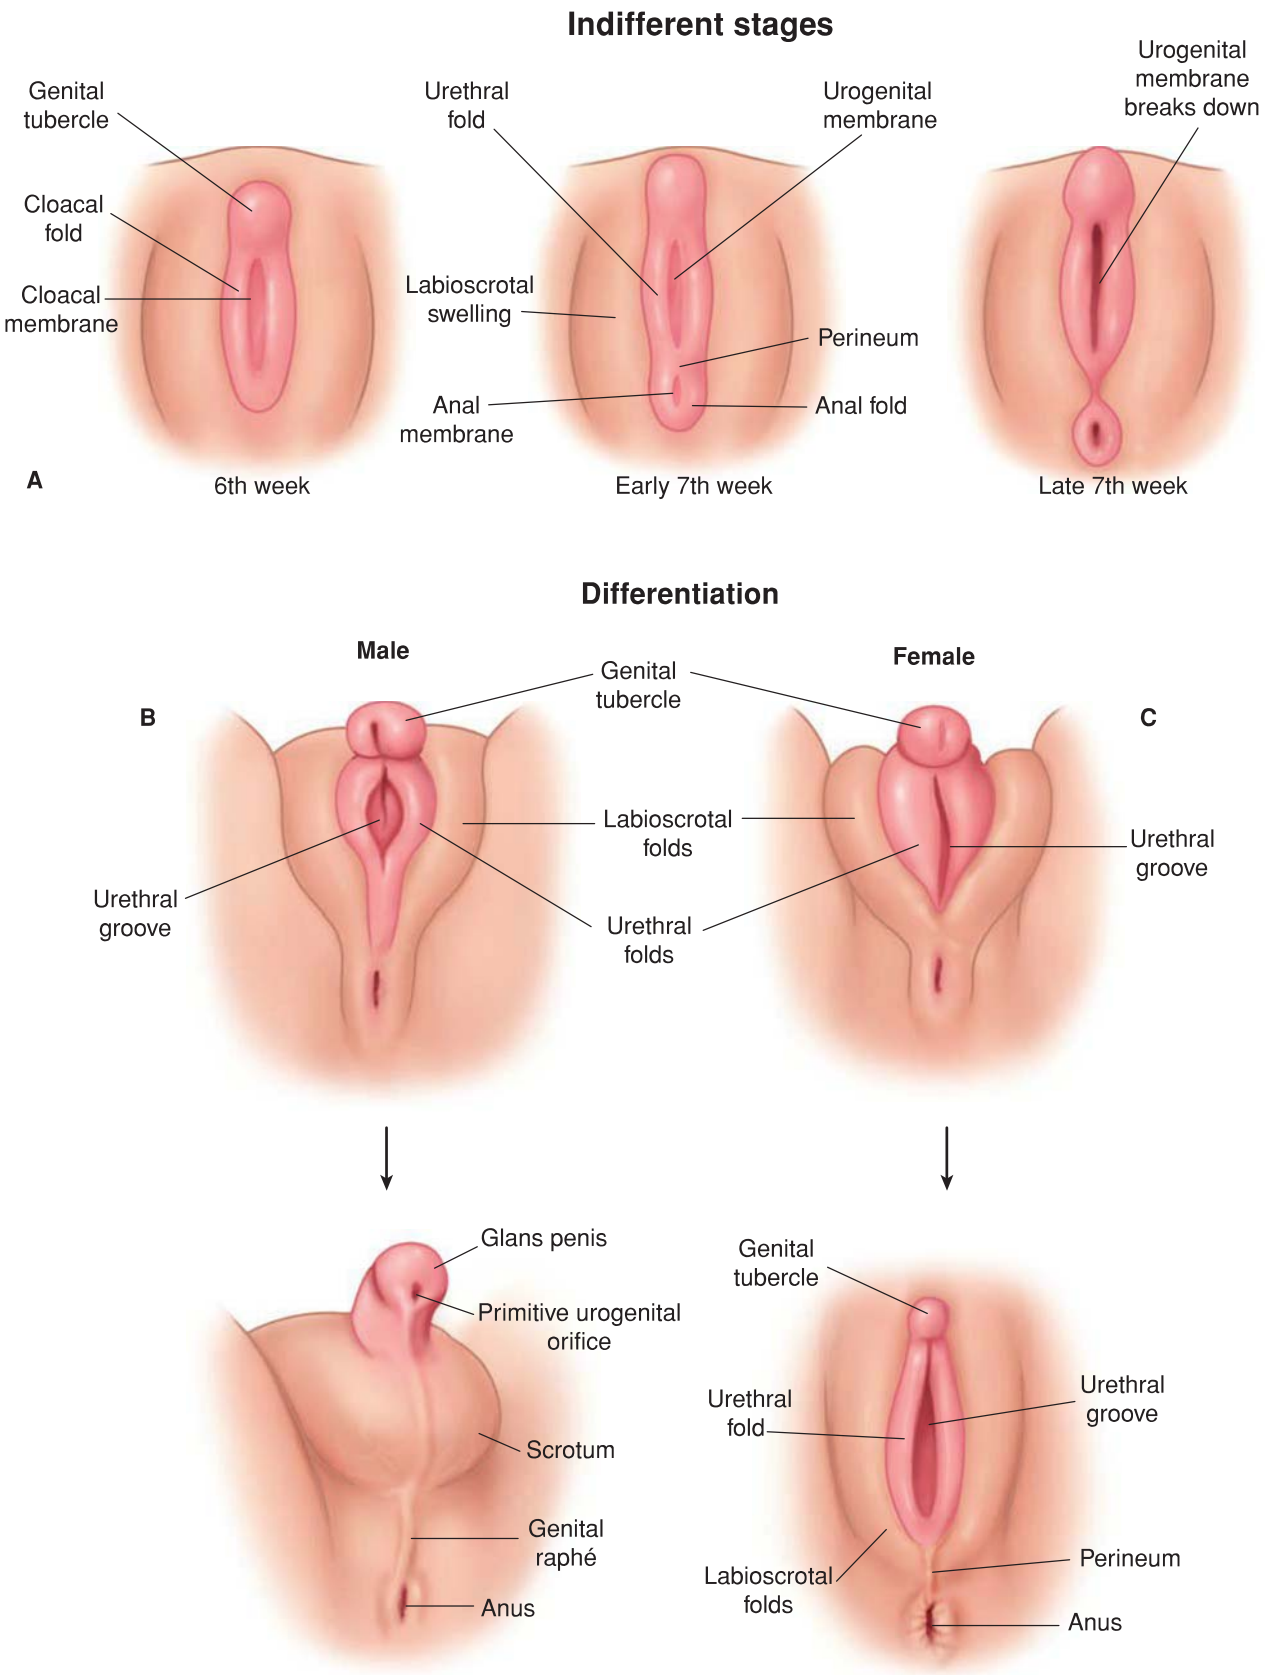

FIGURE 19-5 Development of the external genitalia. **A.** Indifferent stage. **B.** Virilization of external genitalia. **C.** Feminization.

the anal and urethral folds, respectively. Lateral to the urethral folds, genital swellings arise, and these become the labioscrotal folds. Between the urethral folds, the urogenital sinus extends onto the surface of the enlarging genital tubercle to form the urethral groove. By week 7, the urogenital membrane ruptures, exposing the cavity of the urogenital sinus to amnionic fluid.

The genital tubercle elongates to form the phallus in males and the clitoris in females. However, one is not able to visually differentiate between male and female external genitalia until week 12. In the male fetus, DHT forms locally by the 5α-reduction of testosterone. DHT prompts the anogenital distance to lengthen, the phallus to enlarge, and the labioscrotal folds to fuse and form the scrotum. Sonic hedgehog (*SHH*) is a gene that regulates urethral tubularization in males at 14 weeks' gestation (Shehata, 2011). Specifically, DHT and *SHH* expression promote the urethral folds to merge and enclose the penile urethra (Fig. 19-5B). In the female fetus, without DHT, the anogenital distance does not lengthen, and the labioscrotal and urethral folds do not fuse (Fig. 19-5C). The genital tubercle bends caudally to become the clitoris, and the distal urogenital sinus becomes the vestibule of the vagina. The labioscrotal folds create the labia majora, whereas the urethral folds persist as the labia minora.

DISORDERS OF SEX DEVELOPMENT

Definitions

As evident from the prior discussion, differences in sex development may involve the gonads, internal duct system, or external genitalia. Rates vary and approximate 1 in every 1000 to 4500 births (Murphy, 2011; Ocal, 2011).

Formerly, disorders or differences in sex development (DSD) were subdivided as those: (1) associated with gonadal dysgenesis, (2) associated with undervirilization of 46,XY individuals, and (3) associated with prenatal virilization of 46,XX subjects. The nomenclature used to describe atypical sexual differentiation has evolved. Instead of the terms "intersex," "hermaphroditism," and "sex reversal," consensus recommends a new taxonomy based on the umbrella term *disorder of sex development (DSD)* (Lee, 2006). Proposed classification of DSDs are: (1) sex chromosome DSDs, (2) 46,XY DSDs, and (3) 46,XX DSDs (Table 19-2) (Hughes, 2006).

Other terms describe the abnormal phenotypic findings that can be found. First, some DSDs are associated with abnormal, underdeveloped gonads, that is, *gonadal dysgenesis*. With this, if a testis is poorly formed, it is called a *dysgenetic testis*, and if an ovary is poorly formed, it is called a *streak gonad*. In affected patients, the underdeveloped gonad ultimately fails, which is indicated by elevated gonadotropin levels. Another important clinical sequela is that patients bearing a Y chromosome are at high risk of developing a germ cell tumor in the dysgenetic gonad.

A second term, *ambiguous genitalia*, describes genitalia that do not appear clearly male or female. Abnormalities may include hypospadias, undescended testes, micropenis, or enlarged clitoris, labial fusion, and labial mass.

Last, *ovotesticular* defines conditions characterized by ovarian and testicular tissue in the same individual. It was formerly termed *true hermaphroditism*. In these cases, the morphology of the paired gonads can vary, and options that may be paired include a normal testis, a normal ovary, a streak gonad, a dysgenetic testis, or an ovotestis. In the last, both ovarian and testicular elements are combined within the same gonad. The gonadal location varies from abdominal to inguinal to scrotal. With ovotesticular DSDs, the internal ductal system structure depends on the ipsilateral gonad and its degree of determination. Specifically, the amount of AMH and testosterone determines the degree to which the internal ductal system is masculinized or feminized. External genitalia are usually ambiguous due to inadequate testosterone.

TABLE 19-2. Disorders of Sex Development (DSD) Classification

Sex Chromosome DSD
45,X Turner[a]
47,XXY Klinefelter[a]
45,X/46,XY Mixed gonadal dysgenesis
46,XX/46,XY Ovotesticular DSD
46,XY DSD
Testicular development
Pure gonadal dysgenesis
Partial gonadal dysgenesis
Ovotesticular
Testis regression
Androgen production or action
Androgen synthesis
Androgen receptor
LH/hCG receptor
AMH
46,XX DSD

AMH = antimüllerian hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

Sex Chromosome Disorders of Sex Development

Turner and Klinefelter Syndromes

Sex chromosome DSDs typically arise from an abnormal number of sex chromosomes. Of these, Turner and Klinefelter syndromes are most frequently encountered. *Turner syndrome* is caused by de novo loss or severe structural abnormality of one X chromosome in a phenotypic female. It is the most common form of gonadal dysgenesis that leads to primary ovarian insufficiency.

TABLE 19-3. Characteristic Findings of Turner Syndrome

Height 142–147 cm	High-arched palate
Micrognathia	Hearing loss
Epicanthal folds	Webbed neck
Low-set ears	Absent breast development
Shield-like chest	Widely spaced areolae
Cubitus valgus	Short fourth metacarpal
Renal abnormalities	Autoimmune disorders
Aorta coarctation	Autoimmune thyroiditis
Diabetes mellitus	

Most affected fetuses are spontaneously aborted. However, in girls with Turner syndrome who survive, phenotype varies widely, but nearly all affected patients have short stature. This results from lack of one copy of the *SHOX* gene, which resides on the short arm of the X chromosome (Hutson, 2014). The classic stigmata of Turner syndrome are listed in Table 19-3. Of these, cubitus valgus is an elbow deformity that deviates the forearm greater than 15 degrees when the arm hangs at the side. Other Turner syndrome characteristics include cardiac anomalies (especially coarctation of the aorta), renal anomalies, hearing impairment, otitis media and mastoiditis, hypertension, achlorhydria, and autoimmune links to diabetes mellitus, celiac disease, and Hashimoto thyroiditis. This syndrome may be recognized in childhood. However, some patients are not diagnosed until adolescence, when they present with short stature, prepubertal female genitalia, and primary amenorrhea. The last two stem from gonadal failure. The uterus and vagina are normal and are capable of responding to exogenous hormones.

Those with a Turner variant have a structural abnormality of the second X chromosome or have a mosaic karyotype, such as 45,X/46,XX. Indeed, more than half of the girls with this syndrome have chromosomal mosaicism. Those with a Turner variant may exhibit some or all of the syndrome signs. Patients with mosaicism are more likely to have some pubertal maturation.

For adolescents with Turner syndrome and gonadal failure, hormonal treatment is needed to induce puberty, and several protocols are acceptable. The International Turner Syndrome Consensus Group recommends estradiol initiation at ages 11 or 12 years, the use of transdermal estradiol, and gradual dose increases over 2 to 3 years. Progesterone is added after 2 years of treatment or with onset of breakthrough bleeding (Gravholt, 2017).

Women with a Turner variant and remaining ovarian function will typically have rapidly declining fertility. For these individuals, controlled ovarian hyperstimulation coupled with oocyte cryopreservation is an option (Chap. 21, p. 468) (Gravholt, 2017).

Another sex chromosome DSD is *Klinefelter syndrome* (47,XXY), which occurs in 1 in 600 births or in 1 to 2 percent of all males. These individuals tend to be tall, undervirilized males with gynecomastia and small, firm testes. They have significantly reduced fertility from hypogonadism due to gradual testicular cell loss that begins shortly after testis determination (Nistal, 2016). These men carry higher risks for germ cell tumors, osteoporosis, hypothyroidism, diabetes mellitus, breast cancer, and cognitive and psychosocial problems (Aksglaede, 2013). The most common genotype of Klinefelter syndrome is XXY, although variants exist with differing numbers of X chromosomes.

Chromosomal Ovotesticular DSD

Several karyotypes can create a coexistent ovary and testis, and thus ovotesticular DSD is found in all three DSD categories (see Table 19-2). In the sex chromosome DSD group, ovotesticular DSD may arise from a 46,XX/46,XY karyotype. Here, an ovary, testis, or ovotestis may be paired. The phenotype mirrors that for ovotesticular DSDs in general (p. 412).

For others in the sex chromosome DSD group, ovotesticular DSD may develop from a chromosomal mosaic such as 45,X/46,XY. With this karyotype, a picture of *mixed gonadal dysgenesis* shows a streak gonad on one side and a dysgenetic or normal testis on the other. The phenotypic appearance ranges from undervirilized male to ambiguous genitalia to Turner syndrome stigmata.

46,XY Disorders of Sex Development

Insufficient androgen exposure of a fetus destined to be a male leads to 46,XY DSD, formerly called *male pseudohermaphroditism*. The karyotype is 46,XY, and testes are frequently present. The uterus is generally absent as a result of normal embryonic AMH production by Sertoli cells. These patients are most often sterile from abnormal spermatogenesis and have a small phallus that is inadequate for sexual function. As seen in Table 19-2, etiology of 46,XY DSD may stem from abnormal testis development or from abnormal androgen production or action.

46,XY Gonadal Dysgenesis

This spectrum of abnormal gonad underdevelopment includes pure or complete, partial, or mixed 46,XY gonadal dysgenesis (see Table 19-2). These are defined by the amount of normal testicular tissue and by karyotype.

Of these, *pure gonadal dysgenesis* results from a mutation in *SRY* or in another gene with testis-determining effects (*DAX1, SF-1, CBX2*) (Hutson, 2014). This leads to underdeveloped dysgenetic gonads that fail to produce androgens or AMH. Formerly named *Swyer syndrome*, the condition creates a normal prepubertal female phenotype and a normal müllerian system due to absent AMH.

Partial gonadal dysgenesis defines those with gonad development intermediate between normal and dysgenetic testes. Depending on the percentage of underdeveloped testis, wolffian and müllerian structures and genital ambiguity are variably expressed.

Mixed gonadal dysgenesis is one type of ovotesticular DSD. One gonad is streak and the other is a normal or a dysgenetic testis. Of affected individuals, a 46,XY karyotype is found in 15 percent (Nistal, 2015). The phenotypic appearance is wide ranging as with partial gonadal dysgenesis.

Last, *testicular regression* can follow initial testis development. A broad phenotypic spectrum is possible and depends on the timing of testis failure.

Because of the potential for germ cell tumors in dysgenetic gonads and intraabdominal testes, affected patients routinely have been advised to undergo gonadectomy (Chap. 36, p. 758).

Abnormal Androgen Production or Action

In some cases, 46,XY DSD may stem from abnormalities in: (1) testosterone biosynthesis, (2) luteinizing hormone (LH) receptor function, (3) AMH function, or (4) androgen receptor action. First, as evident from Figure 16-5, (p. 339), the sex steroid biosynthesis pathway can suffer enzymatic defects that block testosterone production. Depending on the timing and degree of blockade, undervirilized males or phenotypic females may result. Potential defective enzymes include steroid acute regulatory protein (StAR), cholesterol side-chain cleavage enzyme (P450scc), 3β-hydroxysteroid dehydrogenase type II, 17α-hydroxylase/17,20 desmolase (P450c17a), and 17β-hydroxysteroid dehydrogenase. The last two enzyme deficiencies can also cause congenital adrenal hyperplasia, and hypertension is a common feature in P450c17a deficiency. In addition to these central enzymatic defects, peripherally, abnormal 5α-reductase type 2 enzyme action leads to impaired conversion of testosterone to DHT. DHT is the active androgen in peripheral tissues, and undervirilization results.

Second, hCG/LH receptor abnormalities within the testes can lead to Leydig cell aplasia/hypoplasia and impaired testosterone production. In contrast, disorders of AMH and AMH receptors result in *persistent müllerian duct syndrome (PMDS)*. Affected patients appear as males but have a persistent uterus and fallopian tubes due to failed AMH action.

Last, the androgen receptor may be defective and result in androgen insensitivity syndrome (AIS). The estimated incidence of AIS ranges from 1 in 13,000 to 1 in 41,000 live births (Bangsboll, 1992; Blackless, 2000). Mutations produce a nonfunctional receptor that will not bind androgen or is unable to initiate full transcription once bound. As a result, resistance to androgens may be complete and female external genitalia are found. Alternatively, an incomplete form is associated with varying degrees of virilization and genital ambiguity. Milder forms of AIS have been described in men with severe male factor infertility and poor virilization.

Patients with complete androgen-insensitivity syndrome (CAIS) appear as phenotypically normal females at birth. They often present at puberty with primary amenorrhea. More recently, individuals may be identified when prenatal genetic testing does not match the phenotypic appearance during antenatal ultrasound or at birth. External genitalia appear normal; scant or absent pubic and axillary hair are noted; the vagina is shortened; and the uterus and fallopian tubes are absent. However, these girls develop breasts during pubertal maturation due to abundant androgen-to-estrogen conversion. Testes may be palpable in the labia or inguinal area or may be found intraabdominally.

Prior recommendation for gonadectomy after puberty in females with CAIS has now come into question. Namely, gonads of affected individuals carry a relatively low risk of tumor development (gonadoblastoma and seminoma), and these tumors tend to be easily treated (Patel, 2016). Moreover, in affected individuals, gonadectomy leads to perceived adverse symptoms. Preventively, no evidence-based protocol adequately monitors retained gonads for the development of tumor (Chavhan, 2008). If gonadectomy is undertaken, estrogen is replaced to reach physiologic levels, and a functional vagina created either by serial mechanical dilation or by surgical vaginoplasty. Adequate estrogen replacement in these patients maintains breast development and bone mass and provides relief from vasomotor symptoms.

46,XX Disorders of Sex Development

As seen in Table 19-2, etiology of 46,XX DSD may stem from abnormal ovarian development or from excess androgen exposure.

Abnormal Ovarian Development

Disorders of ovarian development in those with a 46,XX complement include: (1) gonadal dysgenesis, (2) testicular DSD, and (3) ovotesticular DSD. With *46,XX gonadal dysgenesis*, streak gonads develop similar to Turner syndrome. These lead to hypogonadism, prepubertal normal female genitalia, and normal müllerian structures. However, other Turner stigmata are absent.

With *46,XX testicular DSD*, several possible genetic mutations lead to testis-like formation within the ovary (streak gonad, dysgenetic testis, or ovotestis). Defects may stem from *SRY* translocation onto one X chromosome. In individuals without *SRY* translocation, other genes with testis-determining effects are most likely present or activated. These include *WNT4, RSPO1,* or *CTNNB1* gene defects or *SOX9* gene duplication (Ocal, 2011). *SRY* guides the gonad to develop along testicular lines, and testicular hormone function is near normal. Production of AMH prompts müllerian system regression, and androgens promote development of the wolffian system and external genitalia masculinization. Spermatogenesis, however, is absent due to a lack of certain genes on the long arm of the Y chromosome. These individuals are not usually diagnosed until puberty or during infertility evaluation.

With *46,XX ovotesticular DSD*, individuals possess a unilateral ovotestis with a contralateral ovary or testis, or bilateral ovotestes. Phenotypic findings depend on the degree of androgen exposures and mirror those for other ovotesticular DSDs (p. 412).

Androgen Excess

Discordance between gonadal sex (46,XX) and the phenotypic appearance of external genitalia (masculinized) may result from excess fetal androgen exposure. This was previously termed *female pseudohermaphroditism*. In affected individuals, the ovaries and female internal ductal structures such as the uterus, cervix, and upper vagina are present. Thus, patients are potentially fertile. The external genitalia, however, are virilized to a varying degree depending on the amount and timing of androgen exposure. The three embryonic structures that are commonly affected by elevated androgen levels or ovarian development disorders are the clitoris, labioscrotal folds, and urogenital sinus. As a result, virilization may range from modest clitoromegaly to posterior labial fusion and development of a phallus with a penile urethra. Degrees of virilization can be described by the Prader score,

which ranges from 0 for a normal-appearing female to 5 for a normal, virilized male.

Fetal, placental, or maternal sources may provide the excessive androgen levels. Maternally derived androgen excess may come from virilizing ovarian tumors such as luteoma and Sertoli–Leydig cell tumor or from virilizing adrenal tumors. Fortunately, these neoplasms infrequently cause fetal effects because of the tremendous ability of placental syncytiotrophoblast to convert C_{19} steroids (androstenedione and testosterone) to estradiol via the enzyme aromatase (Mahendroo, 2018). As another source, drugs such as testosterone, danazol, norethindrone, and other androgen derivatives may cause fetal virilization.

Of fetal sources, exposure can also arise from fetal congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency from *CYP21* mutation. This is a frequent cause of virilization, and its incidence approximates 1 in 14,000 live births (White, 2000). Early antepartum maternal dexamethasone therapy can ameliorate virilization, however, this practice is controversial (New, 2012). Namely, unless preimplantation genetic testing is undertaken, a significant number of unaffected fetuses are treated to ameliorate one case of ambiguous genitalia (Speiser, 2018). In addition, androgen excess and ambiguous genitalia can be seen with fetal 11-beta hydroxylase and 3-beta hydroxysteroid dehydrogenase deficiencies, from *CYP11B1* and *HSD3B2* gene mutations, respectively (Fig. 16-5, p. 339). Mutations of the *POR* gene also can disorder steroidogenesis. Cytochrome POR is a protein that transfers electrons to important cytochrome P450 enzymes and steroidogenic enzymes. Severely affected female neonates with *POR* gene mutations are virilized because of defective aromatase activity and because of the diversion of 17-hydroxyprogesterone to DHT by a "backdoor" androgen pathway (Fukami, 2013).

Of placental sources, placental aromatase deficiency from fetal *CYP19* gene mutation causes an accumulation of placental androgen and underproduction of placental estrogens. Consequently, both the mother and the 46,XX fetus are virilized (Murphy, 2011).

Gender Assignment

At birth, gender assignment of the normal newborn usually involves a simple assessment of the external genitalia. Delivery of a newborn with DSD is a potential medical emergency. It also poses a psychosocial, diagnostic, medical, and possibly surgical challenge for a multispecialty medical team. For the unprepared obstetrician in the labor room, ambiguous external genitalia in a newborn can be a stressful situation, which if poorly handled, can create possible long-lasting psychosexual and social ramifications for the individual and family. Ideally, as soon as the neonate with ambiguous genitalia is stable, parents are encouraged to hold the child. The newborn is referred to as "your baby" and not as "it" or "he/she." When discussing ambiguous development, other suggested terms used include phallus, gonads, folds, and urogenital sinus to reference underdeveloped structures. The obstetrician explains that the genitalia are incompletely formed and emphasizes the seriousness of the situation and the need for rapid consultation and laboratory testing (Fig. 19-6). During family education, the need for accurate determination of gender and sex of rearing is emphasized.

Because similar or identical phenotypes may have several etiologies, diagnosis of a specific DSD may require several diagnostic tools (Ocal, 2011). Neonatal evaluation interrogates: (1) the ability to palpate gonads in the labioscrotal or inguinal regions, (2) the ability to palpate uterus during rectal examination, (3) phallus size, (3) genitalia pigmentation, and (4) presence of other syndromic features. The newborn's metabolic condition is assessed, and hyperkalemia, hyponatremia, and hypoglycemia may indicate CAH. The mother is examined for signs of hyperandrogenism (Thyen, 2006).

Pediatric endocrinologists or ideally a multidisciplinary DSD team that includes a pediatric endocrinologist, geneticist, pediatric gynecologist, pediatric urologist, and psychologist or therapist is consulted as soon as possible. DSD evaluation incorporates hormone level measurement, imaging, cytogenetic studies, and in some cases endoscopic, laparoscopic, and gonadal biopsy. Sonography shows the presence or absence of müllerian/wolffian structures and can locate the gonads. This imaging is ideally performed shortly after birth. With this timing, maternal hormones have already enlarged neonatal müllerian structures, which renders them easier to visualize. Sonography also can identify associated malformation such as renal abnormalities. Genetic evaluation includes karyotyping, fluorescent in situ hybridization (FISH), and, more recently, specific molecular studies to screen for mutations or gene dosage imbalances.

The psychologic and social implications of gender assignment and those relating to treatment are important and require a multidisciplinary approach. The current intense debate on the management of patients with DSD focuses on four major issues. These are etiologic diagnosis, gender assignment, indications for and timing of genital surgery, and disclosure of medical information to the patient (Daaboul, 2001; de Vries, 2007). Discussions include the need for hormonal stimulation at puberty and potential later surgical reconstruction.

DEFECTS OF THE BLADDER AND PERINEUM

The bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. Normally, an ingrowth of mesoderm between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal musculature and the pelvic bones. Without reinforcement, the cloacal membrane may prematurely rupture. Bladder exstrophy is a complex and severe pelvic malformation due to premature rupture of this cloacal membrane and subsequent failure of the membrane to be reinforced by an ingrowth of mesoderm. Depending on the defect size and developmental stage at rupture, possible defects are bladder exstrophy, cloacal exstrophy, or epispadias.

Of these, bladder exstrophy is characterized by an exposed bladder lying outside the abdomen. Associated findings commonly include abnormal external genitalia and a widened symphysis pubis, caused by the outward rotation of the innominate bones. Stanton (1974) noted that 43 percent of 70 females with bladder exstrophy had associated reproductive tract

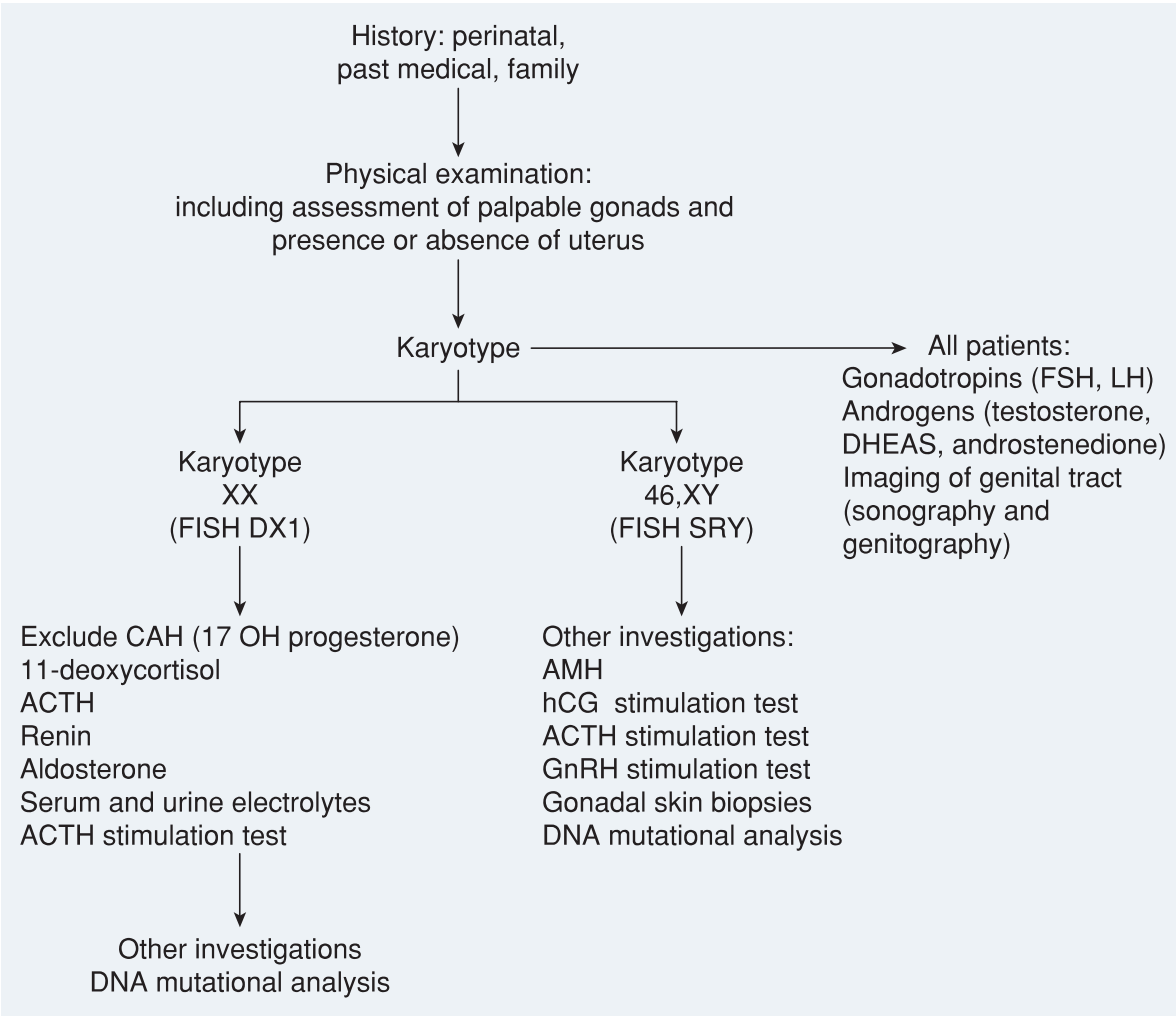

FIGURE 19-6 One algorithm for investigating disorders of sexual development. anomalies. The urethra and vagina are typically short, and the vaginal orifice is frequently stenotic and displaced anteriorly. The clitoris is duplicated or bifid, and the labia, mons pubis, and clitoris are divergent. The uterus, fallopian tubes, and ovaries are typically normal except for occasional müllerian duct fusion defects.

A complex approach is required to achieve acceptable urinary continence and external genitalia reconstruction (Laterza, 2011). Staged surgical closure of the exstrophy is currently performed in the first 4 years of life (Massanyi, 2013). Vaginal dilation or vaginoplasty may be required to allow satisfactory intercourse in mature females (Jones, 1973). Long term, the defective pelvic floor may predispose women to uterine prolapse (Nakhal, 2012).

DEFECTS OF THE CLITORIS

Congenital abnormalities of the clitoris are unusual but include clitoral duplication, clitoral cysts, and clitoral enlargement from excess androgen exposure. Clitoral duplication, also known as *bifid clitoris*, is rare and usually develops in association with bladder exstrophy or epispadias (Elder, 1992).

In those with epispadias, visibly apparent anomalies include a widened, patulous urethra; absent or bifid clitoris; flattened mons pubis; and labia that do not fuse anteriorly. Vertebral abnormalities and diastases of the pubic symphysis are also commonly associated. Female epispadias can be divided into three types—vestibular, subsymphyseal, and retrosymphyseal—which are differentiated by the type of urethral involvement (Schey, 1980). Female phallic urethra is another clitoral anomaly, and the phallic urethra opens at the clitoral tip (Sotolongo, 1983).

Epidermal cysts may be found on the clitoris, and inversion of epidermal cells beneath the dermis or subcutaneous tissue is the presumed pathogenesis. Cysts can reach 1 to 5 cm in diameter. Surgical removal of the cyst is the preferred treatment. Vasculature and nerve supply preservation during this procedure is important to sexual health (Johnson, 2013).

Clitoral enlargement noted at birth is suggestive of fetal exposure to excessive androgens. However, it simply may reflect

ethnic variation (Jarrett, 2015; Phillip, 1996). In addition, in premature neonates, the clitoris may appear large, but it does not change size and appears to regress as the infant grows. Other causes of newborn clitoromegaly include breech presentation with vulvar swelling, chronic severe vulvovaginitis, and neurofibromatosis (Dershwitz, 1984; Greer, 1981).

For individuals with DSD, clitoral reduction surgery is currently very controversial and has been declared a form of torture by the United Nations (2013). Furthermore, Human Rights Watch (2017) has urged a moratorium on such surgeries. No evidence-based research supports early surgery compared with surgery performed once the individual can make an informed decision. If surgery is performed, it should be done by skilled pediatric urologists, and preservation of vasculature and nerve supply is essential.

HYMENEAL DEFECTS

The hymen is the membranous vestige of the junction between the sinovaginal bulbs and the urogenital sinus (see Fig. 19-4). It generally perforates during fetal life to establish a connection between the vaginal lumen and the perineum. Various hymeneal abnormalities include imperforate, microperforate, annular, septate, cribriform (sievelike), naviculate (boatlike), or septate types (Fig. 19-7) (Breech, 1999). Imperforate hymen follows failure of the inferior end of the vaginal plate to canalize, and its incidence approximates 1 in 1000 to 2000 females (Parazzini, 1990). Although typically sporadic, imperforate hymen in multiple family members has been reported (Stelling, 2000; Usta, 1993).

If the hymen is imperforate, blood from endometrial sloughing or mucus accumulates in the vagina. During the neonatal period, significant amounts of mucus can be secreted secondary to maternal estradiol stimulation. The newborn may have a bulging, translucent yellow-gray mass at the vaginal introitus. This condition is termed hydro/mucocolpos. Most cases are asymptomatic and resolve as the mucus is reabsorbed and estrogen levels decline. However, large hydro/mucocolpos may cause respiratory distress or may obstruct the ureters, resulting in hydronephrosis or life-threatening acute renal failure (Breech, 2009; Nagai, 2012).

After menarche, adolescents with imperforate hymen present with trapped menstrual blood behind the hymen, which creates a bluish bulge at the introitus. With cyclic menstruation, the vaginal canal greatly distends, and the cervix may dilate and allow formation of a hematometra and hematosalpinx. Cyclic pain, amenorrhea, abdominal pain mimicking acute abdomen, and difficulty with urination or defecation may be presenting symptoms (Bakos, 1999). Moreover, retrograde menstruation can lead to development of endometriosis. Other obstructive reproductive tract anomalies may present similarly. Indeed, without a bulging membrane, the clinical constellation instead may reflect a transverse vaginal septum or vaginal agenesis, which are not suitably treated by hymenectomy.

Patients with microperforate, cribriform, or septate hymen will typically complain of menstrual irregularities or difficulty with tampon placement or intercourse. Microperforate or imperforate hymen may be corrected when diagnosed and is illustrated in Section 43-17 (p. 978). Many advocate repair

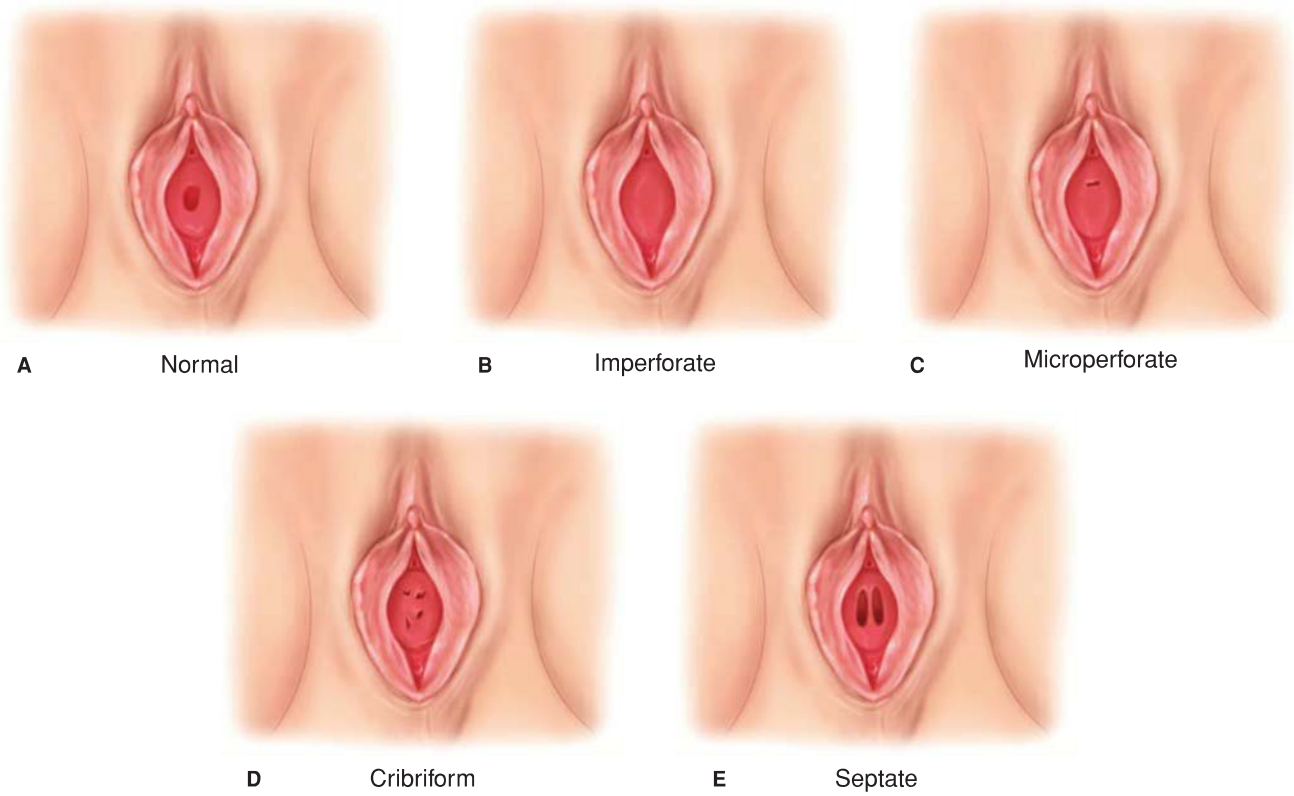

FIGURE 19-7 Types of hymens. **A.** Normal. **B.** Imperforate. **C.** Microperforate. **D.** Cribriform. **E.** Septate.

when estrogen is present to improve tissue healing, either in infancy or after thelarche, but before menarche. This timing avoids the formation of hematocolpos and possible hematometra. Importantly, clinicians should avoid needle aspiration of a hematocolpos for diagnosis or treatment. Aspiration may seed the retained blood with bacteria and raise infection risks. Moreover, recurrent hematocolpos secondary to inadequate drainage is common following needle aspiration alone.

Hymeneal cysts in the newborn must be differentiated from an imperforate hymen with hydro/mucocolpos (Nazir, 2006). These cysts typically are associated with a visible vaginal opening and may regress spontaneously (Berkman, 2004). They may also be treated by incision and drainage. Simple puncture also has been successfully performed.

TRANSVERSE VAGINAL SEPTUM

Transverse vaginal septa are believed to arise from failed müllerian duct fusion or failed canalization of the vaginal plate (Fig. 19-8) (Rock, 1982). The anomaly is uncommon, and Banerjee (1998) reported an incidence of 1 in 70,000 females. A septum may be obstructive, with mucus or menstrual blood accumulation, or nonobstructive.

Transverse vaginal septum can develop at any level within the vagina (Williams, 2014). Those in the upper vagina correspond to the junction between the vaginal plate and the caudal end of the fused müllerian ducts (see Fig. 19-4). Septal thickness may vary but typically is thin (1 cm). Thicker septa can measure 5 to 6 cm, and these tend to lie nearer the cervix (Rock, 1982).

In neonates and infants, obstructive transverse vaginal septum has been associated with fluid and mucus collection in the upper vagina. The resulting mass may be large enough to compress abdominal or pelvic organs. In addition, pyomucocolpos, pyometria, and pyosalpinges may develop from ascension of vaginal or perineal bacteria through small septal perforations (Breech, 1999). In contrast to other müllerian duct defects, transverse vaginal septum is infrequently associated with urologic abnormalities.

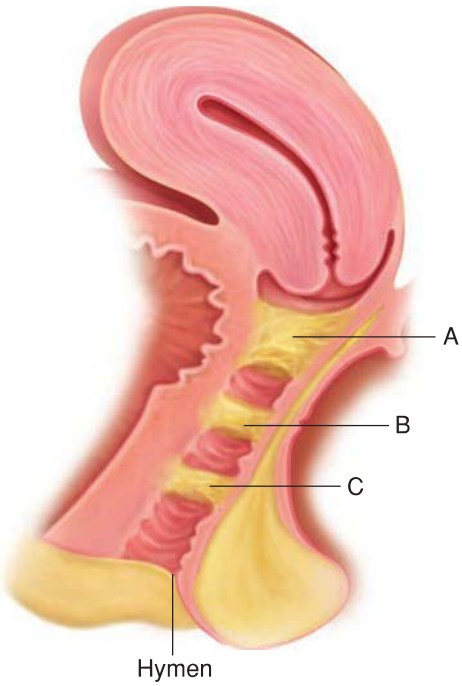

FIGURE 19-8 Potential locations of transverse vaginal septa are indicated and marked **(A–C)**.

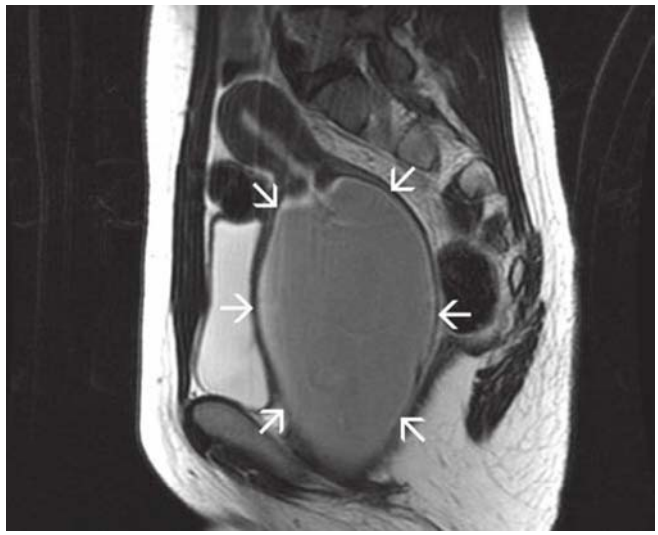

FIGURE 19-9 Magnetic resonance image of complete low transverse septum with obstruction. Marked hematocolpos is identified (*arrows*) in this 13-year-old female. The relatively low signal intensity on the T2-weighted images is consistent with subacute blood. The uterus is seen above the hematocolpos. (Reproduced with permission from Dr. Doug Sims.)

Patients with transverse vaginal septum usually present with symptoms similar to those of imperforate hymen. The diagnosis is suspected when an abdominal or pelvic mass is palpated or when a foreshortened vagina and inability to identify the cervix is encountered. Diagnosis is confirmed by either sonography or magnetic resonance (MR) imaging. MR imaging is most helpful prior to surgery to determine the septal thickness and depth (Fig. 19-9). In addition, MR imaging may identify whether a cervix is present, and thereby help differentiate a high vaginal septum from cervical agenesis.

Surgical repair technique depends on septal thickness, and skin grafts or buccal mucosal grafts may occasionally be necessary to cover the defect left by excision of very thick septa. Smaller septa may be removed by excision followed by end-to-end anastomosis of the upper and lower vagina as described in Section 43-25 (p. 993).

LONGITUDINAL VAGINAL SEPTUM

A longitudinal vaginal septum results from defective lateral fusion or incomplete reabsorption of the caudal central portion of the müllerian ducts. These septa may be partial or extend the complete vaginal length. Longitudinal septa are generally seen with partial or complete duplication of the cervix and uterus. They may also accompany anorectal malformations. Renal abnormalities are common.

Affected individuals complain of difficulty with intercourse. Vaginal bleeding may occur despite placement of a tampon, because the tampon is placed in only one of the duplicated

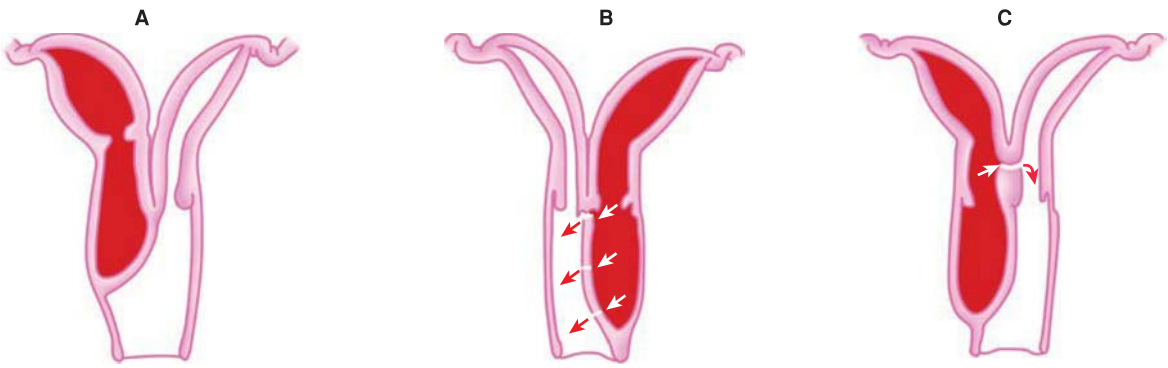

FIGURE 19-10 Uterine didelphys with obstructed hemivagina. **A.** Complete obstruction. **B.** Partial vaginal communication. **C.** Partial uterine communication.

vaginas. Nonobstructed forms can be managed conservatively unless dyspareunia develops. However, there are obstructive longitudinal vaginal septa (Fig. 19-10) (Rock, 1980). Typically, the patient presents in adolescence with normal menarche, but reports worsening, monthly unilateral vaginal and pelvic pain from outflow obstruction (Carlson, 1992). During examination, a patent vagina and cervix are noted, but a unilateral vaginal and pelvic mass can be palpated. Obstructed hemivagina is almost universally associated with ipsilateral renal agenesis. The triad of uterine didelphys, obstructed hemivagina, and ipsilateral renal anomaly is the OHVIRA syndrome, also known as *Herlyn-Werner-Wunderlich syndrome*.

Surgical correction of a longitudinal vaginal septum is described in Section 43-25 (p. 993). It consists of excision of the obstructing septum, taking precautions to avoid the urethra/bladder and rectum. With obstructive cases, sonographic guidance during excision can help identify the distended upper vagina (Breech, 2009).

CONGENITAL VAGINAL CYSTS

In each sex, the müllerian or wolffian ducts marked for degeneration normally do regress, but vestigial remnants can be found and may become clinically apparent. Thus, laterally located cysts may be mesonephric (wolffian) duct remnants. In contrast, the lower vagina derives from the urogenital sinus, which may give rise to congenital vestibular cysts (Heller, 2012).

Remnant cysts are typically located in the anterolateral wall of the vagina, although they may be found at various locations along its length. Most are asymptomatic and benign, measure 1 to 7 cm in diameter, and do not require surgical excision. Deppisch (1975) described 25 cases of symptomatic congenital vaginal cysts and reported a wide range of symptoms. These included dyspareunia, vaginal pain, difficulty with tampon use, urinary symptoms, and palpable mass. If these cysts become infected and intervention is required during the acute phase, cyst marsupialization is preferred.

Occasionally, a remnant cyst may cause chronic symptoms and warrant excision. Pelvic MR imaging can assist prior to surgery to determine the extent of the cyst and its anatomic relationship to the ureter or bladder base (Hwang, 2009). Of note, complete vaginal cyst excision may be more difficult than anticipated, as some may extend up into the broad ligament and anatomically approximate the distal course of the ureter.

MÜLLERIAN ANOMALIES

Abnormalities of the uterus may be congenital or acquired and typically present with menstrual dysfunction, pelvic pain, infertility, or early pregnancy loss. Congenital anomalies have a heterogeneous genetic basis, and *WT1*, *Pax2*, *WNT2*, *PBX1*, and *HOX* genes are potentially involved (Hutson, 2014).

Various classification schemes for female reproductive tract anomalies exist, but the most commonly used system was proposed by Buttram and Gibbons (1979) and adapted by the American Society for Reproductive Medicine (former American Fertility Society, 1988). Within this system, six categories organize similar embryonic developmental defects (Fig. 19-11). Moreover, Acien (2009) and Rock (2010) have described types of uterovaginal and cervical malformations that do not adapt to the usual classification systems. Such anomalies are described and drawn in detail in a patient's medical record for future reference.

Most cases are diagnosed during evaluation for obstetric or gynecologic problems, but in the absence of symptoms, most anomalies remain undiagnosed. Because nearly 57 percent of women with uterine defects have successful fertility and pregnancy, the true incidence of congenital müllerian defects may be significantly understated. Nahum (1998) found that the prevalence of uterine anomalies in the general population was 1 in 201 women or 0.5 percent. Dreisler and colleagues (2014) found uterine anomalies in nearly 10 percent of 622 women from the general population undergoing saline-infusion sonography.

Anatomic uterine defects have long been recognized as a cause of obstetric complications. Recurrent pregnancy loss, preterm labor, abnormal fetal presentation, and prematurity constitute the major reproductive problems encountered. *Williams Obstetrics*, 25th edition provides a full discussion of specific müllerian abnormalities and their obstetric importance (Hoffman, 2018). Müllerian defects are also associated with renal anomalies in 30 to 50 percent of cases, and defects include unilateral renal agenesis, severe renal hypoplasia, horseshoe kidney, pelvic kidney, and ectopic or duplicate ureters (Sharara, 1998). Spinal anomalies have been reported in 10 to 12 percent of cases of müllerian anomaly and include wedge,

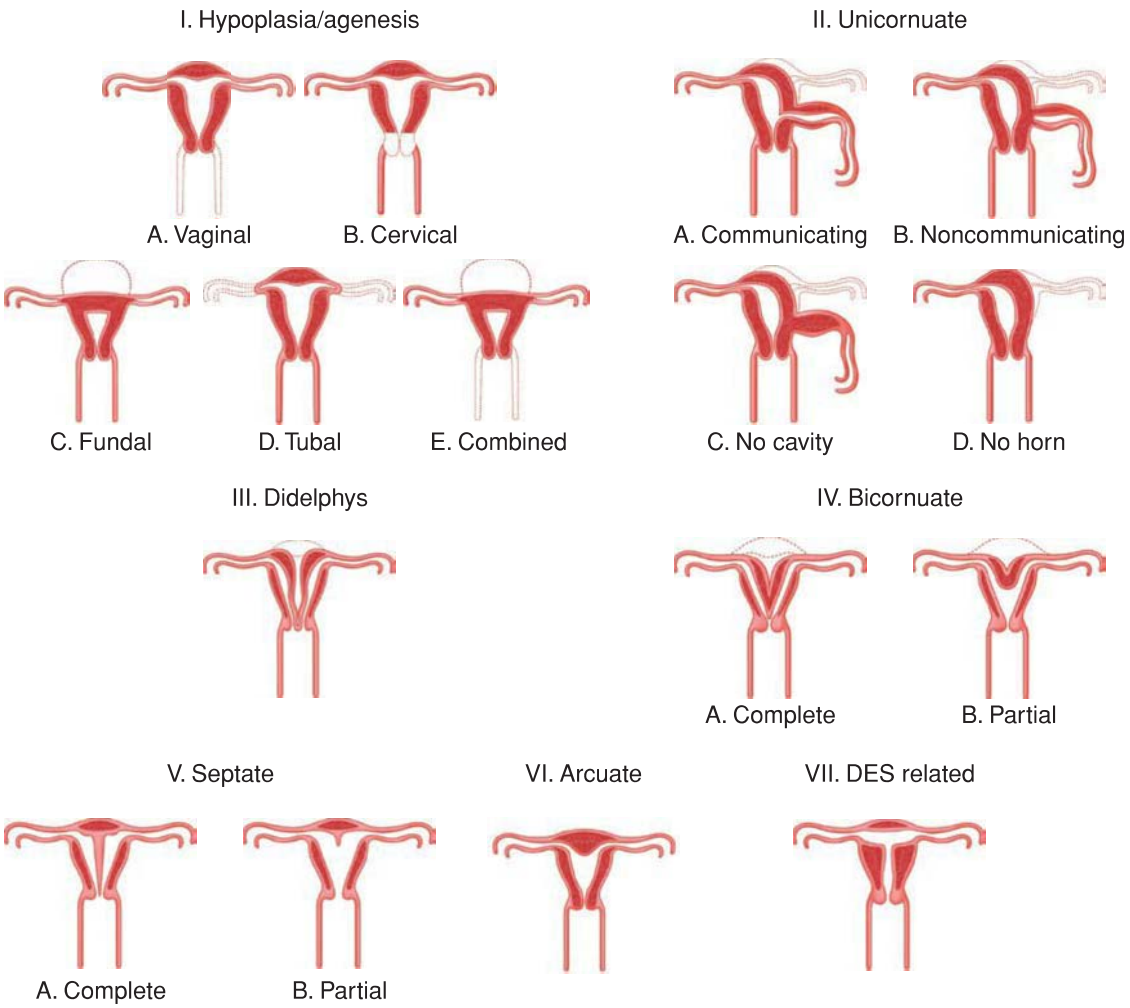

FIGURE 19-11 Classification of müllerian anomalies. (Reproduced with permission from American Fertility Society, Fertil Steril 1988 Jun;49(6):944–55.)

supernumerary, or asymmetric and rudimentary vertebral bodies (Kimberley, 2011). The combination of müllerian and renal aplasia and cervicothoracic somite dysplasia has been described as *MURCS association* (Duncan, 1979).

Depending on a woman's initial complaint, tools to diagnose müllerian anomalies may include hysterosalpingography (HSG), sonography, MR imaging, laparoscopy, and hysteroscopy. Each tool has limitations, but they may be used in combination to completely define anatomy. In women undergoing fertility evaluation, HSG is commonly selected for uterine cavity and tubal patency assessment. That said, HSG poorly defines the external uterine contour and can delineate only patent cavities.

With sonography, transabdominal views may help to maximize the viewing field, but transvaginal sonography (TVS) provides better image resolution. Saline-infusion sonography (SIS) improves delineation of the endometrium and internal uterine morphology, but only with a patent endometrial cavity. Three-dimensional (3-D) sonography can provide uterine images from virtually any angle. Thus, coronal images can be constructed and are essential in evaluating both internal and external uterine contours (Chap. 2, p. 41). Sonography is ideally completed during the luteal phase when the secretory endometrium provides contrast from its increased thickness and echogenicity (Caliskan, 2010). Investigators have reported good concordance between 3-D TVS and MR imaging of müllerian anomalies (Bermejo, 2010; Ghi, 2009).

MR imaging provides clear delineation of both the internal and external uterine anatomy and has a reported accuracy of up to 100 percent for evaluating müllerian anomalies (Fedele, 1989; Pellerito, 1992). Moreover, complex anomalies and commonly associated secondary diagnoses such as renal or skeletal anomalies can be concurrently evaluated.

Last, in some women undergoing an infertility evaluation, hysteroscopy and laparoscopy may be selected to assess for müllerian anomalies; screen for endometriosis, which is often coexistent; and exclude other tubal or uterine cavity pathologies (Puscheck, 2008; Saravelos, 2008).

Segmental Müllerian Hypoplasia or Agenesis

Some form of müllerian aplasia, hypoplasia, or agenesis affects 1 in every 4000 to 10,000 females and is a common cause of primary amenorrhea (American College of Obstetricians and Gynecologists, 2018). Uterine agenesis follows failed development of the lower portion of the müllerian ducts during embryogenesis and usually leads to absence of the uterus, cervix, and upper part of the vagina (Oppelt, 2006). Variants may

display absence of the upper vagina but presence of the uterus. Normal ovaries are found, and affected individuals otherwise develop as phenotypically normal females and present with primary amenorrhea.

Vaginal Atresia

Females with vaginal atresia lack the lower portion of the vagina, but otherwise have normal pubertal maturation and external genitalia (see Fig. 19-11). Embryologically, the urogenital sinus fails to contribute its expected caudal portion of the vagina (Simpson, 1999). As a result, the lower portion of the vagina, usually one-fifth to one-third of the total length, is replaced by 2 to 3 cm of fibrous tissue. In some individuals, however, vaginal atresia may extend to near the cervix.

Since most affected women have normal external genitalia and upper reproductive tract organs, vaginal atresia does not often become apparent until menarche. Adolescents generally present shortly after physiologic menarche with cyclic pelvic pain due to hematocolpos or hematometra. On physical examination, the hymeneal ring is normal, and no bulging membrane is seen. Proximal to the ring, only a vaginal dimple or small pouch is found. A rectoabdominal examination confirms midline organs. Additionally, sonographic or MR imaging will display upper reproductive tract organs. Of options, MR imaging is the most accurate diagnostic tool, as length of the atresia, amount of upper vaginal dilation, and presence of a cervix can be identified. A cervix in such cases distinguishes vaginal atresia from müllerian agenesis. Laparoscopy, however, is often necessary when anatomy cannot be fully evaluated with radiographic studies. Treatment follows that for müllerian agenesis.

Cervical Agenesis

Women with congenital absence of the cervix typically also lack the upper vagina. The uterus, however, usually develops normally (see Fig. 19-11). In addition to agenesis, Rock (2010) has described various forms of cervical dysgenesis.

Women with cervical agenesis initially present similarly to patients with other reproductive tract obstructive anomalies, that is, with primary amenorrhea and cyclic pelvic pain. If a functional endometrium is present, a patient may have a distended uterus, and endometriosis may develop secondary to retrograde menstrual flow. A single midline uterine fundus is the norm, although bilateral hemiuteri have also been described (Dillon, 1979).

Radiographic studies, sonography, and MR imaging aid anatomy delineation. If imaging demonstrates an obstructed uterus, hysterectomy has been recommended by some (Rock, 1984). Niver (1980) and others report creation of an epithelialized endocervical tract and vagina. However, significant morbidity, that includes infection, recurrent obstruction requiring hysterectomy, and death due to sepsis, has been reported with establishment of such a vaginal-uterine connection (Casey, 1997; Rock, 2010). Alternatively, conservative management with a gonadotropin-releasing hormone (GnRH) agonist or with combination oral contraceptive pills may be used to suppress retrograde menses and possible endometriosis until a patient is ready for reproduction options (Doyle, 2009). Thus, the uterus may be retained for possible reproductive potential. Thijssen and associates (1990) reported a successful pregnancy using zygote intrafallopian tube transfer in a patient with cervical agenesis. Gestational surrogacy offers another viable option for these women.

Müllerian Agenesis

Congenital absence of both the uterus and vagina is termed *müllerian aplasia*, *müllerian agenesis*, or *Mayer-Rokitansky-Küster-Hauser syndrome (MRKH)*. In classic müllerian agenesis, patients have a shallow vaginal pouch, measuring only 1 to 2 inches deep. In addition, the uterus, cervix, and upper part of the vagina are absent. Typically, normal ovaries persist, given their separate embryonic source, and a portion of the distal fallopian tubes is present. Most patients with müllerian agenesis have only small rudimentary müllerian bulbs without endometrial activity. However, in 2 to 7 percent of women with this condition, active endometrium develops and patients typically present with cyclic abdominal pain (American College of Obstetricians and Gynecologists, 2018). In these cases, surgical excision of symptomatic rudimentary bulbs is required. With müllerian agenesis, traditional conception is impossible, but pregnancy may be achieved using oocyte retrieval, fertilization, and gestational surrogacy. Uterine transplantation also has resulted in successful live births (Brännström, 2015, 2018).

Evaluation for associated congenital renal or other skeletal anomalies is essential in individuals with müllerian hypoplasia or agenesis. As noted, approximately 15 to 36 percent of women with uterine agenesis also have defects of the urinary system, and 12 percent may have scoliosis. Skeletal malformations observed include spina bifida, sacralization (partial fusion of L5 to the sacrum), sacral bone lumbarization (nonfusion of the first and second sacral segments), and cervical vertebral anomalies. Noted earlier, MURCS syndrome displays müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (Oppelt, 2006). Cardiac and neurologic abnormalities are less common but include ventricular septal defects and unilateral hearing problems.

Treatment. One treatment goal for most affected women is creation of a functional vagina. This may be accomplished conservatively or surgically. Of the several conservative approaches, each attempts to progressively invaginate the vaginal dimple to create a canal of adequate size. Graduated hard glass dilators were initially recommended by Frank (1938). Ingram (1981) modified the Frank method by affixing the dilators to a bicycle seat mounted upon a stool. This affords patients hand mobility for other activities during the 30 minutes to 2 hours spent each day for passive dilation (American College of Obstetricians and Gynecologists, 2018). Currently, firm silicon dilators are available through several medical vendors and commercially available vibrating dilators are recommended by some providers. The involvement of a pelvic floor physical therapist may assist the patient in comfortably performing dilation herself (Patel, 2018). A vagina may also be created with repeated coitus. Overall, vaginal dilation techniques are successful in forming a functional vagina in 90 percent of cases (Croak, 2003; Roberts, 2001).

Surgical procedures are a more immediate solution to neovagina creation, and several are available. The Vecchietti procedure places a dilating sphere at the vaginal dimple. The sphere is attached to two wires, which are guided through the potential neovaginal space and subsequently follow an extraperitoneal course along the inner abdominal wall. Illustrated in Section 43-26 (p. 995), the wires then exit onto the lower abdomen. Here, they are placed on continuous tension, which is increased daily to stretch the vagina over approximately 1 week (Vecchietti, 1965).

Another method used commonly by gynecologists is the McIndoe vaginoplasty (McIndoe, 1950). Illustrated in Section 43-26 (p. 995), a canal is created within the connective tissue between the bladder and rectum. A split-thickness skin graft obtained from the patient's buttocks or thigh is then used to line the neovagina.

Modifications of the McIndoe procedure use buccal mucosa, human amnion, musculocutaneous flaps, or absorbable adhesion barriers to line the neovaginal space (Ashworth, 1986; Lin, 2003; Motoyama, 2003; Williams, 1964). Instead, Shears (1960) created the neovaginal space and allowed the space to epithelialize naturally. The Davydov procedure pulls pelvic peritoneum from the pelvis into the neovaginal space (Davydov, 1969).

All of these methods require a commitment to scheduled postoperative dilation to avoid significant vaginal stricture (Breech, 1999). Accordingly, these procedures only are considered if the patient is mature and willing to adhere to a postoperative regimen of regular intercourse or manual dilation with dilators.

To avoid these postoperative requirements, pediatric surgeons often use a segment of bowel to create the vagina. These colpoplasties use sigmoidal or ileal segments and require abdominal entry and bowel anastomosis. Many patients complain of a persistent vaginal discharge from the gastrointestinal mucosa.

Unicornuate Uterus

Failure of one müllerian duct to develop and elongate results in a unicornuate uterus. This anomaly is common, and Zanetti (1978) found an incidence of 14 percent in a series of 1160 uterine anomalies. With unicornuate uterus, a functional uterus, normal cervix, and normal round ligament and fallopian tube are found on one side. On the contralateral side, müllerian structures develop abnormally, and agenesis or more frequently a rudimentary uterine horn is identified (see Fig. 19-11). A rudimentary horn may communicate or more commonly not communicate with the unicornuate uterus. In addition, the endometrial cavity of the rudimentary horn may be obliterated or may contain some functioning endometrium. Active endometrium in a noncommunicating horn will eventually be symptomatic with cyclic unilateral pain and possibly with hematometra.

Women with a unicornuate uterus have a higher incidence of infertility, endometriosis, and dysmenorrhea (Fedele, 1987; Heinonen, 1983). On physical examination, the uterus is often markedly deviated, but imaging is frequently needed to further define horn anatomy (p. 420). Renal sonography is performed, because 40 percent of women with a unicornuate uterus also have some degree of renal agenesis, usually ipsilateral to the anomalous side (Rackow, 2007). If anatomy is unclear, then MR imaging is selected to add information.

Women with unicornuate uterus have impaired pregnancy outcomes. A review of studies reveals a spontaneous abortion rate of 36 percent, a preterm delivery rate of 16 percent, and a live birth rate of 54 percent (Rackow, 2007). Other obstetric risks include malpresentation, fetal-growth restriction, fetal demise, and prematurely ruptured membranes (Chan, 2011; Reichman, 2009).

The pathogenesis of pregnancy loss associated with unicornuate uterus is incompletely understood. Reduced uterine capacity or anomalous distribution of the uterine artery is suggested (Burchell, 1978). Moreover, cervical incompetence may contribute to the risk for premature delivery and late-trimester abortion. Accordingly, a unicornuate uterus is suspected in any woman with a history of pregnancy loss, premature delivery, or abnormal fetal lie.

No surgeries are currently available to enlarge the unicornuate uterus cavity. Some obstetricians recommend prophylactic cervical cerclage, but adequate trials assessing outcome are lacking. Selection of a gestational surrogate may circumvent these anatomic limitations. Other patients, however, seem to carry their pregnancies longer with each subsequent gestation and may eventually reach fetal viability prior to labor.

Pregnancy may also occur in the rudimentary horn. In noncommunicating horns, this is thought to result from the intraabdominal transit of sperm from the contralateral fallopian tube. Pregnancy in a cavitary horn regardless of communication is associated with a high rate of uterine rupture, typically prior to 20 weeks (Rolen, 1966). Because of the high maternal morbidity secondary to intraperitoneal hemorrhage, excision of a cavitary rudimentary horn is indicated (Heinonen, 1997; Nahum, 2002). In many cases, this can be completed laparoscopically (Spitzer, 2009). Moreover, rudimentary horn pregnancy can be similarly treated in those with appropriate laparoscopic skills (Kadan, 2008).

If the rudimentary horn is obliterated, removal is not routinely recommended. Salpingectomy on the side with the obliterated rudimentary horn has been suggested to prevent ectopic pregnancy in women with a unicornuate uterus. However, the ectopic pregnancy risk is low.

Uterine Didelphys

A didelphic uterus results from failed fusion of the paired müllerian ducts. This anomaly is characterized by two separated uterine horns, each with an endometrial cavity and uterine cervix. A longitudinal vaginal septum runs between the two cervices in most cases. Heinonen (1984) reported that all 26 women with uterine didelphys in his series had a longitudinal vaginal septum. Occasionally, one hemivagina is obstructed by an oblique or transverse vaginal septum (see Fig. 19-10) (Hinckley, 2003). Uterine didelphys should be suspected if a longitudinal vaginal septum or if two separate cervices are discovered. Imaging is recommended to confirm the diagnosis.

Pregnancies develop in one of the two horns, and of the major uterine malformations, the didelphic uterus has a good

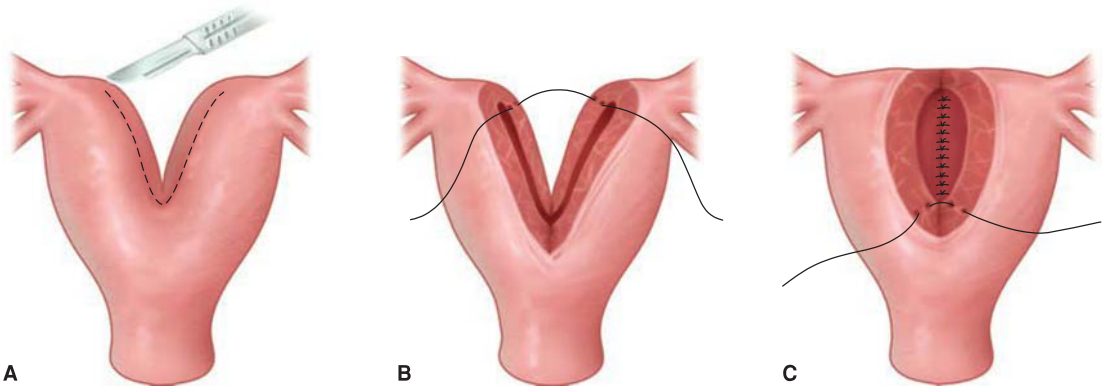

FIGURE 19-12 Strassman metroplasty is one of several techniques of bicornuate uterus repair. **A.** Excision of intervening uterine wall. **B.** Reapproximation of posterior uterine wall with a layer of myometrial sutures. **C.** Reapproximation of the anterior wall is closed similarly. Following placement of myometrial sutures, a layer of subserosal sutures is placed in the anterior and posterior walls.

reproductive prognosis. Compared with the unicornuate uterus, although the potential for uterine growth and capacity appears similar, uterine didelphys probably has an improved blood supply from collateral connections between the two horns. Alternatively, improved fetal survival may be secondary to earlier diagnosis, which favors more intensive prenatal care (Patton, 1994). Heinonen (2000) followed 36 women with uterus didelphys long term and found that 34 of 36 women (94 percent) who wanted to conceive had at least one pregnancy, and they produced 71 pregnancies. Of these pregnancies, 21 percent were spontaneously aborted, and 2 percent were ectopic. The rate for fetal survival was 75 percent; for prematurity, 24 percent; for fetal-growth restriction, 11 percent; for perinatal mortality, 5 percent; and for cesarean delivery, 84 percent. In this series, pregnancy located more often (76 percent) in the right horn than in the left. Because the spontaneous abortion rate mirrors that of women with normal uterine cavities, surgical procedures in response to pregnancy loss are rarely indicated. Thus, surgery is reserved for highly selected patients in whom repeated late-trimester losses or premature delivery has occurred with no other apparent etiology.

Bicornuate Uterus

This anomaly is caused by incomplete fusion of the müllerian ducts. It is characterized by two separate but communicating endometrial cavities and a single uterine cervix. Failed fusion may extend to the cervix, resulting in a complete bicornuate uterus. It may be partial and cause a milder abnormality. Women with a bicornuate uterus can expect reasonable success—approximately 60 percent—in delivering a living child. As with many uterine anomalies, premature delivery is a substantial obstetric risk. Heinonen and colleagues (1982) reported a 28-percent abortion rate and a 20-percent incidence of premature labor in women with a partial bicornuate uterus. Women with a complete bicornuate uterus had a 66-percent incidence of preterm delivery and a lower fetal survival rate.

Radiologic discrimination of bicornuate and septate uteri can be challenging. However, it is important because a septate uterus is easily treated with hysteroscopic septum resection. Widely diverging horns seen during HSG may suggest a bicornuate uterus. Namely, an intercornual angle >105 degrees suggests bicornuate uterus, whereas one <75 degrees indicates a septate uterus. However, fundal contour is not seen with HSG. Instead, 3-D sonography allows internal and external uterine assessment, and criteria for differentiating septate and bicornuate uteri are illustrated in Figure 2-25 (p. 42). Thus, sonography and HSG are acceptable imaging techniques for initial investigation. MR imaging may be indicated for complicated anatomy.

Surgical reconstruction of the bicornuate uterus may be considered in women with multiple spontaneous abortions in whom no other causative factors are identified. Strassman (1952) described the surgical technique that unified equal-sized endometrial cavities (Fig. 19-12). Two main disadvantages include required cesarean delivery to prevent uterine rupture in a subsequent pregnancy and the high rate of postoperative pelvic adhesion formation leading to subsequent infertility. Case series describe improved live-birth rates following metroplasty (Candiani, 1990; Lolis, 2005). However, in one series that had a small case-controlled group, metroplasty did not improve the live birth rate (Kirk, 1993). Given the lack of robust data and the attendant risk of uterine rupture, metroplasty is best reserved for women with recurrent pregnancy loss from no other identifiable cause.

Septate Uterus

Following fusion of the müllerian ducts, failure of their medial segments to regress can create a permanent septum within the uterine cavity. Its contours can vary widely and depend on the amount of persistent midline tissue. The septum can project minimally from the uterine fundus or can extend completely to the cervical os. Septa also can develop segmentally, resulting in partial communications within the partitioned uterus (Patton, 1994). The histologic structure of septa ranges from fibrous to fibromuscular.

The true incidence of these anomalies is not known because they are usually detected only in women with obstetric complications. Although it does not predispose to higher rates of preterm labor or cesarean delivery, septate uterus is associated with a marked increase in spontaneous abortion rates

(Heinonen, 2006). Woelfer and colleagues (2001) reported a first-trimester spontaneous abortion rate for septate uterus of 42 percent. Moreover, early pregnancy loss is significantly more common with a septate than with a bicornuate uterus (Proctor, 2003).

This extraordinarily high pregnancy wastage likely results from partial or complete implantation on a largely avascular septum, from uterine cavity distortion, or from associated cervical or endometrial abnormalities. Septate uterus may rarely cause fetal malformation, and Heinonen (1999) described three newborns with a limb-reduction defect born to women with septate uterus.

Septate uterus can best be diagnosed with 3-D TVS, SIS, or MR imaging, because these display the uterine cavity and fundal contour (Chap. 2, p. 41) (American Society for Reproductive Medicine, 2016). If the presumptive diagnosis is a septate uterus, hysteroscopy can add information.

In women with recurrent pregnancy loss or infertility, hysteroscopic septum resection can improve live-birth rates and clinical pregnancy rates, respectively (Daly, 1983, 1989; DeCherney, 1983; Israel, 1984). Typically, operative hysteroscopy is combined concurrently with laparoscopic guidance or transabdominal sonographic surveillance to reduce the risk of uterine perforation (Section 44-16, p. 1065). Compared with abdominal metroplasty, hysteroscopic resection leads to higher live-birth rates, avoids mandatory cesarean delivery, and offers shorter convalescence, lower pelvic adhesion rate, and less operative morbidity (Fayez, 1986; Patton, 1994).

Arcuate Uterus

An arcuate uterus displays only mild deviation from normal uterine development. Anatomic hallmarks include a slight midline septum within a broad fundus, sometimes with minimal fundal cavity indentation. Most clinicians report no impact on reproductive outcomes. Conversely, Woelfer and colleagues (2001) found excessive second-trimester losses and preterm labor. Surgical resection is indicated only if excessive rates of pregnancy loss are encountered and other etiologies for recurrent spontaneous abortion have been excluded.

Diethylstilbestrol-Induced Reproductive Tract Abnormalities

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed to an estimated 3 million pregnant women in the United States from the 1940s through the early 1960s. The drug was prescribed to treat abortion, preeclampsia, diabetes, hot flashes, and preterm labor but was later found to be ineffective for these indications (Massé, 2009). Instead, Herbst and coworkers (1971) found that DES exposure in utero was linked to the development of a "T-shaped" uterus and an increased incidence of clear cell adenocarcinomas of the vagina and cervix. The risk of this vaginal malignancy approximates 1 in 1000 exposed daughters. Daughters also have higher risks of developing vaginal and cervical intraepithelial neoplasia, suggesting that DES exposure could affect gene regulation (Herbst, 2000). DES suppresses the *WNT4* gene and alters *Hox* gene expression in mouse müllerian ducts. This provides a plausible mechanism for the uterine abnormalities, vaginal adenosis, and rarely, carcinoma observed in exposed patients (Massé, 2009).

During normal development, the vagina is originally lined by a glandular epithelium derived from the müllerian ducts. By the end of the second trimester, this layer is replaced by squamous epithelium extending up from the urogenital sinus. Failure of the squamous epithelium to completely line the vagina is termed *vaginal adenosis*. Typically appearing red and granular, its common symptoms include vaginal irritation, discharge, and intermenstrual bleeding—in particular, postcoital bleeding. Moreover, adenosis is frequently associated with vaginal clear cell adenocarcinoma.

Genitourinary malformations can follow in utero DES exposure and include those of the cervix, vagina, uterine cavity, and fallopian tubes. Transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars ("cockscomb cervix") have been found. Women with cervicovaginal abnormalities are more likely to have uterine anomalies, such as smaller uterine cavities, shortened upper uterine segments, and "T-shaped" or irregularly shaped cavities (Barranger, 2002). Fallopian tube abnormalities include shortened and narrowed dimensions and absent fimbria. HSG remains the primary imaging tool for identification of these anomalies.

Males exposed to DES in utero can have structural abnormalities. Cryptorchidism, testicular hypoplasia, microphallus, and hypospadias have been reported (Hernandez-Diaz, 2002).

Women exposed to DES, in general, have impaired conception rates (Senekjian, 1988). Their reduced fertility is poorly understood but is associated with cervical hypoplasia and atresia. Of those who do conceive, the incidences of spontaneous pregnancy loss, ectopic pregnancy, and preterm delivery are higher, again particularly in those with associated structural abnormalities (Goldberg, 1999). Now, decades after DES use was halted, most affected women are past childbearing age, but higher rates of earlier menopause and breast cancer have been reported (Hatch, 2006; Hoover, 2011).

FALLOPIAN TUBE ANOMALIES

The fallopian tubes develop from the unpaired distal ends of the müllerian ducts. Congenital anomalies of the fallopian tube include accessory ostia, complete or segmental absence of the tube, and several embryonic cystic remnants. The remnants of the mesonephric duct in the female include a few blind tubules in the mesovarium, the *epoophoron*, and similar ones adjacent to the uterus, collectively called the *paroophoron* (see Fig. 19-2F) (Moore, 2013). The epoophoron or paroophoron may develop into clinically identifiable cysts. Remnants of the müllerian duct may be found along its embryologic course. The most common is a small, cystic structure attached by a pedicle to the distal end of the fallopian tube, the *hydatid of Morgagni* (Zheng, 2009).

Paratubal cysts are frequent incidental discoveries during gynecologic operations for other abnormalities or are found on sonographic examination (Chap. 10, p. 229). They may be of mesonephric, paramesonephric, or mesothelial origin. Most cysts are asymptomatic and slow growing and are discovered during the third and fourth decades of life. Large paratubal cysts found

in adolescents are thought to derive from wolffian remnants and are associated with excess androgens (Dietrich, 2017).

In utero exposure to DES has been associated with various tubal abnormalities (p. 424). Short, tortuous tubes or ones with shriveled fimbria and small ostia have been linked to infertility (DeCherney, 1981).

OVARIAN ANOMALIES

A *supernumerary ovary* is an ectopic ovary that has no connection with the broad, uteroovarian, or infundibulopelvic ligaments (Wharton, 1959). This rare gynecologic anomaly may be located in the pelvis, retroperitoneum, paraaortic area, colonic mesentery, or omentum. Aberrant migration of part of the genital ridge after incorporation of germ cells describes one theory (Printz, 1973). The term *accessory ovary* describes excess ovarian tissue nearby and connected to a normally placed ovary. Wharton (1959) estimated that both accessory ovary and supernumerary ovary were rare but frequently associated genitourinary tract anomalies.

An absent ovary, with or without an associated tube, may result from congenital agenesis or from ovarian torsion with necrosis and reabsorption (Eustace, 1992; James, 1970). The incidence has been suggested to be approximately 1 in 11,240 women (Sivanesaratnam, 1986).

EVALUATION FOR FEMALE ANATOMIC ABNORMALITIES 437
EVALUATION OF MALE INFERTILITY 442
GENETIC SCREENING 445
CONCLUSION 446
REFERENCES 446

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse of reasonable frequency. It can be subdivided into *primary infertility*, that is, no prior pregnancies, and *secondary infertility*, referring to infertility following at least one prior conception.

Conversely, fecundability is the ability to conceive, and data from large population studies show that a monthly probability of conceiving is 20 to 25 percent (Table 20-1) (Guttmacher, 1956; Mosher, 1991). In those attempting conception, more than 85 percent will be pregnant by 1 year.

Infertility is common and affects 10 to 15 percent of reproductive-aged couples. Of note, even without treatment, approximately half of women will conceive in the second year of attempting. According to the National Survey of Family Growth, the percentage of married women who reported infertility fell from 8.5 percent in 1982 to 6.0 percent in 2006 to 2010. In comparison, the percentage of women aged 15 to 44 years who had ever used infertility services rose from 9 percent in 1982 to 12 percent in 2002 (Chandra, 2013, 2014). Rates of fertility measures for men and women remained similar from 2011 to 2015 (Martinez, 2018). Interpretation of these data is complicated by ongoing changes in marriage rates, intentional delays in childbearing, and socioeconomic and educational status changes. Nevertheless, well-publicized successes in infertility treatment now give patients greater hope that medical intervention can help them achieve their goal, and this has prompted them to seek evaluation and treatment in growing numbers.

TABLE 20-1. Fecundity of Normal Couples Over Time

Several factors result in substantial disparities in access to infertility care. Diagnosis of conditions in men may be delayed or missed due to social factors that hold the female primarily responsible for conception and childbearing. Also, infertility insurance coverage is unequal between the sexes (Chu, 2019; Dupree, 2016; Farland, 2016). In addition, marked disparities in access to fertility care have been noted for unmarried, homosexual, and transgender individuals. The ethical concerns raised by these discrepancies are addressed in several recent reports by the American Society for Reproductive Medicine (2013a, 2015a, d).

Most couples are more correctly considered to be *subfertile*, rather than infertile, as they will ultimately conceive if given enough time. This concept of subfertility can be reassuring. However, there are obvious exceptions, such as the woman with bilaterally obstructed fallopian tubes or the azoospermic male. In general, infertility evaluation is offered to any couple that has failed to conceive in 1 year. But, several scenarios may prompt earlier intervention. For example, delayed assessment in an anovulatory woman or a woman with a history of severe pelvic inflammatory disease (PID) may not be appropriate. Of particular note, fecundability is highly age-related. A significant decrease begins at approximately age 32 years, and a more rapid decline follows after age 37 (American Society for Reproductive Medicine, 2014a). This decline in conception rates is associated with a rise in poor pregnancy outcome rates, primarily due to higher aneuploidy rates. Thus, most experts agree that evaluation is considered after only 6 months in women older than 35 years.

Prior to initiating infertility treatment, a patient's health status is ideally optimized for an anticipated pregnancy. These issues are best addressed prior to referral to an infertility specialist whenever possible (American College of Obstetricians and Gynecologists, 2019). A complete list of preconceptional topics is provided later in this chapter and in Table 1-17 (p. 19).

Of note, accumulating data suggest that fertility status may be a marker of overall health in both men and women (Cedars, 2017). Phrased differently, the causes of infertility may be physiologically or genetically linked to somatic disorders either through association or by common pathophysiologic mechanisms. As a result, the infertility evaluation may allow early detection, prevention, and intervention for serious chronic diseases.

ETIOLOGY OF INFERTILITY

Successful pregnancy requires a complex sequence that includes ovulation, ovum pick-up by a fallopian tube, fertilization, transport of a fertilized ovum into the uterus, and implantation into a receptive uterine cavity. With male infertility, sperm of adequate number and quality must be deposited at the cervix near the time of ovulation. Remembering these critical events can aid a logical evaluation and treatment strategy.

In general, infertility can be attributed to the female partner one third of the time, the male partner one third of the time, and both partners in the remaining one third. This approximation emphasizes the value of assessing both partners before instituting therapy. Although a complete investigation may not be required before instituting therapy if a clear etiology is present, strong consideration is given to finishing testing if pregnancy is not rapidly achieved. Estimates of the incidence of various causes of infertility are shown in Table 20-2 (American Society for Reproductive Medicine, 2006).

Both partners are urged to attend the initial consultation. This time provides an excellent opportunity to educate about the normal conception process and about methods to optimize their natural fertility. Such efforts may obviate the need for expensive and time-consuming interventions (American Society for Reproductive Medicine, 2017b). Couples are taught the concept of a fertile window for conception. The chance of conception is increased from the 5 days preceding ovulation through the day of ovulation (Fig. 20-1) (Wilcox, 1995). If the male partner has normal semen characteristics, a couple ideally has daily intercourse during this period to maximize the chance of conception. Although sperm concentrations will drop with greater coital frequency, this decline is generally too small to significantly lower the chance of fertilization (Stanford, 2002). Couples are also reminded to avoid oil-based lubricants, which are harmful to sperm. Many myths surround the ability to conceive. Examples, such as the importance of coital position and the need to remain horizontal following ejaculation, can add undue stress to an already stressful situation and should be dispelled.

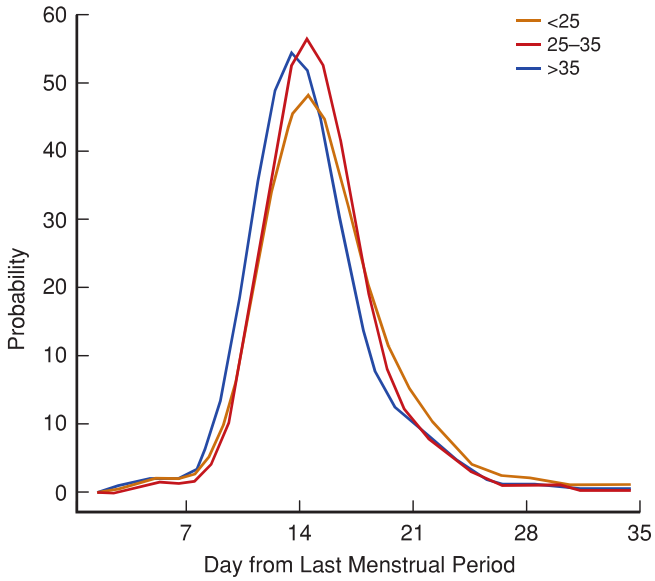

FIGURE 20-1 Day-specific probabilities of conception vary by age group. (Redrawn with permission from Stirnemann, 2013.)

MEDICAL HISTORY

Female History

Gynecologic

As with any medical condition, a thorough history and physical examination is critical (American Society for Reproductive Medicine, 2015b). Specifically, questions cover menstruation characteristics, prior contraceptive use, coital frequency, possible menopause symptoms, and infertility duration. Previous endometriosis, recurrent ovarian cysts, leiomyomas, sexually transmitted diseases, or PID is also pertinent. Because prior conception indicates ovulation and a patent fallopian tube at some point, this history is sought. A prolonged time to conception may suggest borderline fertility and may raise the chance of determining an etiology. Pregnancy complications such as miscarriage, preterm delivery, retained placenta, postpartum dilation and curettage, chorioamnionitis, or fetal anomalies also are recorded. A coital history, including frequency and timing of intercourse, is obtained. Symptoms such as dyspareunia may point to endometriosis and a need for earlier diagnostic laparoscopy for the female partner.

TABLE 20-2. Etiology of Infertility

Male	25%
Ovulatory	27%
Tubal/uterine	22%
Other	9%
Unexplained	17%

Medical and Surgical

The medical history should seek symptoms of hyperprolactinemia or thyroid disease. Symptoms of androgen excess such as acne or hirsutism may point to polycystic ovarian syndrome (PCOS) or, much less commonly, congenital adrenal hyperplasia. Prior chemotherapy or pelvic irradiation may suggest ovarian failure. This is also an excellent opportunity to ensure that all indicated vaccinations are current, as several are contraindicated once pregnancy is achieved (American Society for Reproductive Medicine, 2018a).

Questions regarding medications include over-the-counter agents, such as nonsteroidal antiinflammatory drugs, that may adversely affect ovulation. In most instances, herbal remedies are discouraged. Women are encouraged to take a daily multivitamin with at least 400 μg of folic acid to lower the chance of neural-tube defects. In those with a previously affected child, 4 g is taken orally daily (American College of Obstetricians and Gynecologists, 2017d).

Previous abdominal surgeries, especially if linked to endometriosis or adhesion formation, can lower fertility. As examples, operations for ruptured appendicitis or diverticulitis raise suspicion for pelvic adhesive disease or tubal obstruction or both. Prior cervical conization can diminish cervical mucus and cervical competence. Past uterine surgery can predispose to pain,

bowel obstruction, or intrauterine adhesions with resultant infertility. When planning surgery, reducing adhesion formation is a priority, and meticulous surgical technique and minimally invasive surgical approaches are favored. Surgical adhesion barriers, described in Chapter 40 (p. 855), lower postoperative adhesion rates. However, no strong evidence exists that their use improves fertility, diminishes pain, or lowers bowel obstruction rates (American Society for Reproductive Medicine, 2013b).

Social

A social history focuses on lifestyle factors such as eating habits. Of these, abnormalities in gonadotropin-releasing hormone (GnRH) and gonadotropin secretion are clearly related to body mass indices >25 or <17 (Grodstein, 1994a). An estimated 40 percent of women are obese, and most agree this incidence is rising (Hales, 2018). In these women, infertility is primarily related to a higher incidence of ovulatory dysfunction, but data also suggest that fecundity may be lowered by poorer oocyte quality and altered endometrial function (American Society for Reproductive Medicine, 2015e). Although difficult to achieve, even modest weight reduction in overweight women is correlated with normalized menstrual cycles and subsequent pregnancies. Surgically induced weight loss also has been reported to restore ovulation and menstrual regularity and chance of pregnancy, although continued study is needed (Table 20-3) (Consalvo, 2017; Pilone, 2019; Slopien, 2019).

Accumulating data suggest that cigarette smoking lowers fertility rates (American Society for Reproductive Medicine, 2018c). At least 15 percent of reproductive-aged men and women in the United States smoke cigarettes (Jamal, 2018). The prevalence of infertility is higher, and the time to conception is longer in women who smoke, or even those exposed passively to cigarette smoke. Moreover, smoking's negative effects on female fecundity do not appear to be overcome by assisted reproductive technology (ART) (Klonoff-Cohen, 2001). Toxins in the smoke can accelerate follicular depletion and increase genetic mutations in gametes or early embryos (Zenzes, 2000). Smoking has been linked to higher rates of miscarriage, abruption, fetal-growth restriction, and preterm labor (Dashe, 2018). Vasoconstrictive and antimetabolic properties of some cigarette smoke components such as nicotine, carbon dioxide, and cyanide may lead to placental insufficiency.

The effect of smoking on male fertility is more difficult to discern. Although smokers often have comparatively reduced sperm concentrations and motility, these often remain within the normal range.

Admittedly, current data do not prove causation, but only correlation, between smoking and infertility or adverse pregnancy outcomes. Nevertheless, smoking is discouraged for both male and female partners planning pregnancy. The desire for pregnancy can be a powerful motivator toward cessation (Augood, 1998). Education is the most important first step (Table 20-4). If needed, medical adjuncts such as nicotine replacement therapy, bupropion (Zyban), or varenicline (Chantix) may prove effective (Table 1-4, p. 9).

Alcohol consumption also should be limited. Heavy alcohol intake lowers fertility in women and has been associated with a decline in sperm counts and greater sexual dysfunction in men (Klonoff-Cohen, 2003; Nagy, 1986). A standardized alcoholic drink is typically defined as 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of hard alcohol. Based on several studies, five to eight drinks per week negatively affects female fertility (Grodstein, 1994b; Tolstrup, 2003). As alcohol is also detrimental to early pregnancy, it is prudent to advise patients to avoid excessive alcohol consumption while trying to conceive.

Caffeine is one of the most widely used pharmacologically active substances in the world. Studies evaluating a potential relationship between caffeine and impaired fertility have varied in design and resulted in conflicting findings. One large prospective trial found no association between either total caffeine intake or coffee consumption and fecundability (Hatch, 2012). Despite this, recommendations of caffeine intake moderation in infertile women seem prudent.

Illicit drugs also may affect fecundability and pregnancy outcomes and should be strongly discouraged (American College of Obstetricians and Gynecologists, 2017c). Marijuana use has increased worldwide, and despite limited data, many in the public perceive that cannabis has no health risks (Chang, 2019; Keyhani, 2018). Reassuringly, a recent study found that time to pregnancy was not lengthened by marijuana use in either men or women (Kasman, 2018). However, in a study of 12 million births from 1999 to 2013 in the United States, neonates born to exposed mothers had a higher risk of premature rupture of membranes, prematurity, and intrauterine fetal demise (Petrangelo, 2019).

TABLE 20-3. Effects of Obesity and Environmental Factors on Fertility

Factor	Impact on Fertility
Obesity (BMI >35)	2-fold increase TTC
Underweight (BMI <19)	4-fold increase TTC
Smoking	1.6-fold increase RR
Alcohol (>2/day)	1.6-fold increase RR
Illicit drugs	1.7-fold increase RR
Toxins	1.4-fold increase RR
Caffeine (>250 mg/day)	45% decrease fecundability

BMI = body mass index; RR = relative risk of infertility; TTC = time to conception.

TABLE 20-4. Women's Awareness of Health Risks Associated with Smoking

Smoking Risk	Percentage Aware of Risk
Respiratory disease	99%
Heart disease	96%
Pregnancy complications	91%
Spontaneous abortion	39%
Ectopic pregnancy	27%
Infertility	22%
Early menopause	18%

Environmental Factors

Growing information suggests that some male and female infertility may result from environmental contaminants or toxins (Giudice, 2006). Endocrine-disrupting chemicals (EDCs) such as dioxins and polychlorinated biphenyls have been shown to be reproductive toxicants (Hauser, 2008; Mendola, 2008). Others include agricultural pesticides and herbicides, phthalates (used in making plastic materials), lead, and bisphenol A (used in the manufacture of polycarbonate plastic and resins). EDC exposure is implicated to underlie a broad range of women's reproductive disorders. Lower fecundability and lower birthweight show the most solid evidence for this correlation (Caserta, 2011). Although direct links to infertility in humans are not conclusive, clinicians should counsel patients that environmental exposures to toxic substances are avoided if possible. Currently, data should be discussed carefully to avoid alarm.

Ethnicity and Family History

The ethnic background and family history of both partners influences the need for preconceptional testing. A family history of infertility, recurrent miscarriage, or fetal anomalies may point to a genetic etiology that warrants genetic screening (p. 445). Although the inheritance pattern is complex, data suggest that both PCOS and endometriosis occur in familial clusters. For example, a woman carries an estimated sevenfold greater risk of endometriosis than that of the general population if a single first-degree family member has the disease (Moen, 1993).

Male History

Similar attention is paid to assessing the male partner's potential contribution to infertility (American Society for Reproductive Medicine, 2015c). Questions include pubertal development and sexual function difficulties. Erectile dysfunction, particularly in conjunction with diminished beard growth, may suggest lower testosterone levels. Ejaculatory problems also are evaluated. This includes a search for developmental anomalies such as hypospadias, which could result in suboptimal semen deposition (Gray, 2018).

Sexually transmitted diseases or frequent genitourinary infections, including epididymitis or prostatitis, may lead to vas deferens inflammation and obstruction. Similarly, mumps in an adult can create testicular inflammation and damage spermatogenic stem cells (Beard, 1977). Moreover, prior cryptorchidism, testicular torsion, or testicular trauma may suggest abnormal spermatogenesis (Anderson, 1990; Cobellis, 2014). Compared with fertile males, males with unilateral or bilateral cryptorchidism have fertility rates of 80 percent and 50 percent, respectively (Lee, 1993). Although unclear, the relatively warm intraabdominal temperature may cause permanent stem cell damage. Alternatively, genetic abnormalities that led to the abnormal testis location may also affect sperm production.

A history of varicocele is also obtained. A varicocele consists of dilated veins of the pampiniform plexus of the spermatic cords that drain the testes. Varicoceles are believed to raise scrotal temperature, however, the negative effects of varicoceles on fertility are controversial (American Society for Reproductive Medicine, 2014b; Baazeem, 2011). Although 30 to 40 percent of men seen in infertility clinics are diagnosed with a varicocele, nearly 20 percent of men in the general population are similarly affected. If a varicocele is suspected, it should be evaluated by a urologist, preferably one with a specific interest in infertility. Current guidelines recommend against surgical repair of a nonpalpable, that is, subclinical varicocele for infertility. However, treatment for pain or other symptoms may be warranted (Kohn, 2018).

Spermatogenesis, from stem cell to mature sperm, takes nearly 90 days (Figs. 20-2 and 20-3). Thus, any detrimental event in

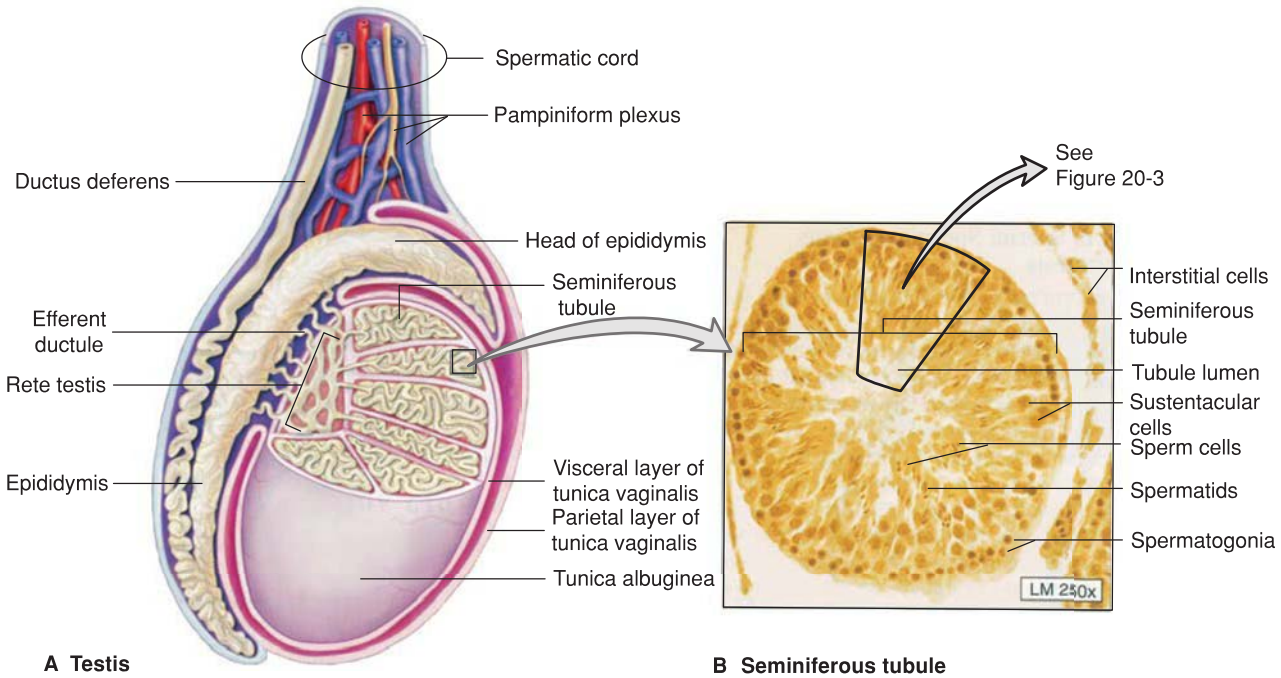

FIGURE 20-2 Male testis. **A.** Gross anatomy of a testis. **B.** Cutaway of the testis reveals the microscopic structure of a seminiferous tubule. (Reproduced with permission from McKinley, 2006.)

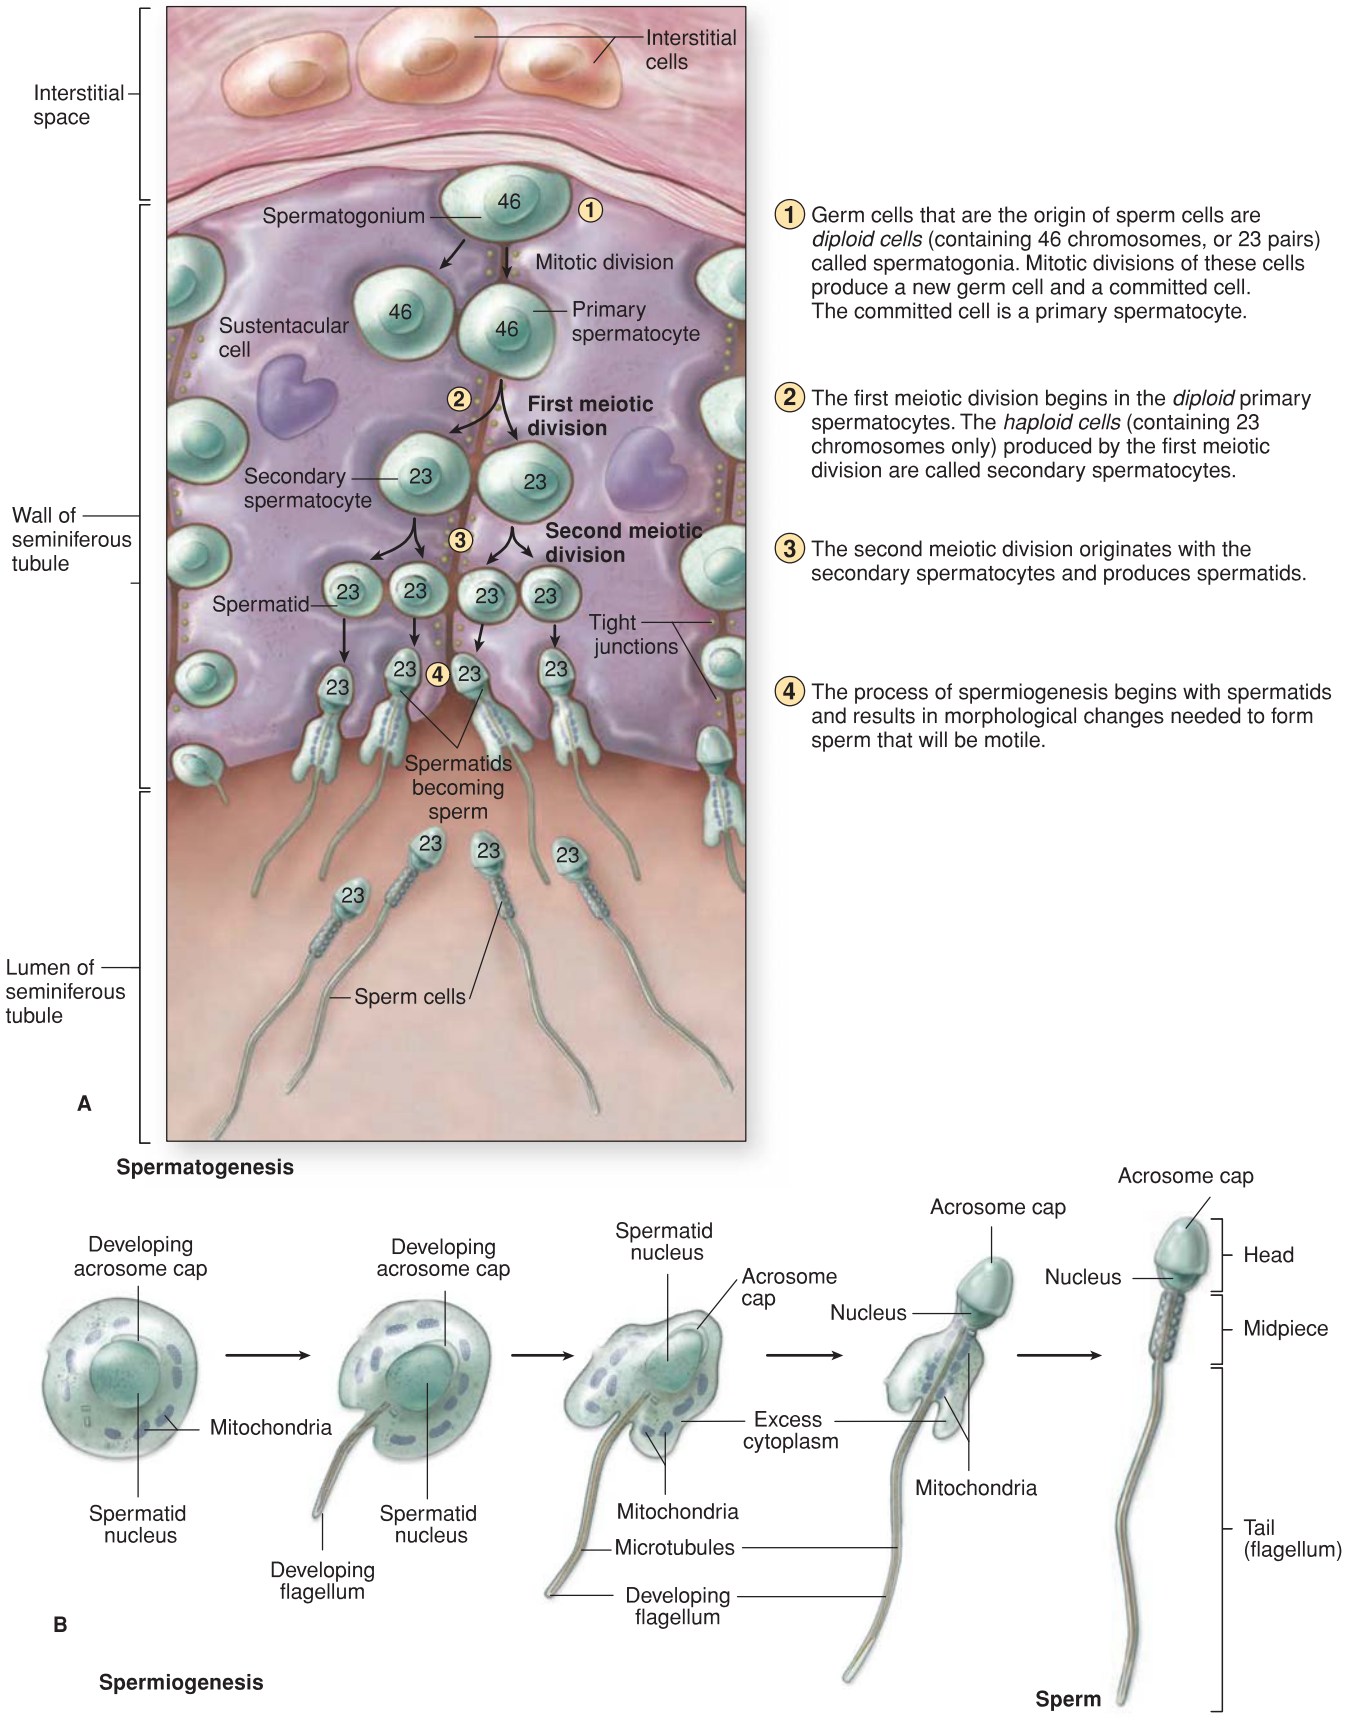

FIGURE 20-3 Male testis. **A.** Cutaway of the seminiferous tubule shows the mitotic and meiotic divisions involved with spermatogenesis. **B.** Structural changes required during spermiogenesis, as sperm cells become spermatids. (Reproduced with permission from McKinley, 2006.)

the prior 3 months can adversely affect semen characteristics (Hinrichsen, 1980; Rowley, 1970). Spermatogenesis is optimal at temperatures slightly below body temperature, hence the location of the testes outside of the pelvis. Illness with high fevers or chronic hot tub use can temporarily impair sperm quality. But, no definitive evidence supports boxer underwear as advantageous.

Medical questions focus on prior chemotherapy or local radiation treatment that may damage spermatogonial stem cells. Hypertension, diabetes mellitus, and neurologic disorders can be associated with erectile dysfunction or retrograde ejaculation. Poor semen quality has been associated with higher rates of diabetes, ischemic heart disease, and mortality and an increased individual and familial cancer risk. These findings suggest semen quality may be a biomarker of overall health (Eisenberg, 2014, 2016; Hanson, 2018b). Excessive weight has been associated with obesity-related secondary hypogonadism, erectile dysfunction, and infertility. Similar to women, rigorous data describing the effects of bariatric surgery on male reproductive health are lacking (Di Vincenzo, 2018).

Several medications are known to worsen semen parameters, including cimetidine, erythromycin, gentamicin, tetracycline, and spironolactone (Sigman, 1997). Moreover, cigarettes, alcohol, illicit drugs, and environmental toxins all adversely affect semen quality (Bracken, 1990; Muthusami, 2005; Ramlau-Hansen, 2007). The rising use of anabolic steroids also decreases sperm production by suppressing the output of intratesticular testosterone (Gazvani, 1997). Although the effects of many medications are reversible, anabolic steroid abuse may lead to lasting or even permanent damage to testicular function.

An exercise history also is obtained. Although the evidence quality is generally low, bicycling has been associated with erectile dysfunction and decreased sperm concentration. Similar effects are suggested in long distance runners (Hwang, 2019).

PHYSICAL EXAMINATION

Examination of the Female Patient

A physical examination may provide many clues to the cause of infertility. Vital signs, height, and weight are recorded. A particularly short stature may reflect a genetic condition such as Turner syndrome. Hirsutism, alopecia, or acne indicates the need to measure androgen levels. Acanthosis nigricans is consistent with insulin resistance associated with PCOS or diabetes or, much less commonly, Cushing syndrome. Galactorrhea is often indicative of hyperprolactinemia. Additionally, thyroid abnormalities are sought. Many of these diagnoses and their management are discussed in greater detail in other chapters (Table 20-5).

A pelvic examination may be particularly informative. Inability to place a speculum through the introitus may raise doubts about coital frequency. The vagina should be moist and rugated, and the cervix should have a reasonable amount of mucus. Both indicate adequate estrogen production. An enlarged or irregularly shaped uterus may reflect leiomyomas, whereas a fixed uterus suggests pelvic scarring due to endometriosis or prior pelvic infection. Uterosacral nodularity or ovarian masses may additionally implicate endometriosis or, less commonly, malignancy.

All women should have cervical cancer screening that is up to date prior to treatment. Negative cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are obtained to ensure that cervical manipulation during evaluation and treatment does not cause ascending infection. The breast examination must be normal, and when indicated by age or family history, a mammogram is obtained prior to initiating hormonal treatment.

Examination of the Male Patient

Most gynecologists will not feel comfortable performing a complete male physical examination. Nevertheless, parts of this evaluation are relatively easy to perform, and a gynecologist at minimum should understand the primary focus of the examination. Normal secondary sexual characteristics that reflect androgen production such as beard growth, axillary and pubic hair, and perhaps male pattern balding should be present. Gynecomastia or eunuchoid habitus may suggest Klinefelter syndrome (De Braekeleer, 1991).

The penile urethra should be at the glans tip for proper semen deposition in the vagina. Testicular length measures at least 4 cm

TABLE 20-5. Chapters with Relevant Information About Infertility

and a minimal testicular volume is 20 mL (Fig. 20-4) (Charny, 1960; Hadziselimovic, 2006). Small testes are unlikely to produce normal sperm numbers. A testicular mass may indicate testicular cancer, which can present as infertility. The epididymis should be soft and nontender to exclude chronic infection. Epididymal fullness may suggest vas deferens obstruction. The prostate should be smooth, nontender, and normal size. Additionally, the pampiniform plexus of veins is palpated for varicocele. Importantly, both vasa deferentia should be palpable. Congenital bilateral absence of the vas deferens is associated with mutation in the gene responsible for cystic fibrosis (Anguiano, 1992).

EVALUATION FOR ANOVULATION

The infertility evaluation can be conceptually simplified into confirmation of: (1) ovulation, (2) normal female reproductive tract anatomy, and (3) normal semen characteristics. The specifics regarding evaluation of each of these categories are detailed in the following sections and in Table 20-6.

TABLE 20-6. Infertility Testing

Etiology	Evaluation
Ovulatory function/ovarian reserve	Ovulation predictor kit Early follicular FSH ± estradiol level Antimüllerian hormone (AMH) Endocrine disorders (TSH, prolactin) Ovarian sonography (antral follicle count)
Tubal/pelvic disease	Hysterosalpingography Laparoscopy + chromotubation
Uterine factors	Hysterosalpingography Transvaginal sonography/saline-infusion sonography ± Magnetic resonance imaging Hysteroscopy ± laparoscopy
Male factor	Semen analysis

FSH = follicle-stimulating hormone; TSH = thyroid-stimulating hormone.

Of these, ovulation may be perturbed by abnormalities within the hypothalamus, anterior pituitary, or ovaries. Hypothalamic disorders may be acquired or inherited. Acquired disorders include those due to lifestyle, for example, excessive exercise, eating disorders, or stress. Alternatively, dysfunction or improper migration of the hypothalamic gonadotropin-releasing hormone neurons may be inherited, such as that which occurs in idiopathic hypogonadotropic hypogonadism (IHH) or Kallmann syndrome. Thyroid disease and hyperprolactinemia also may contribute to menstrual disturbances. Measurement of thyroid stimulating hormone (TSH) levels is considered reasonable in any infertile woman to screen for subclinical hypothyroidism, particularly in those with any question regarding menstrual regularity or with a positive family history for thyroid disease (American Society for Reproductive Medicine, 2015f). A full discussion of endocrine-related disorders that result in menstrual disturbances is found in Chapter 16 (p. 359).

Clinical Evaluation

A patient's menstrual history is an excellent predictor of regular ovulation. A woman with cyclic menses at an interval of 25 to 35 days and duration of bleeding of 3 to 7 days is most likely ovulating. Although these numbers vary widely, each woman will have her own normal pattern. Therefore, these figures typically do not vary significantly across cycles for an individual woman.

Probable ovulation is also suggested by *mittelschmerz*, which is midcycle pelvic pain associated with ovulation, or by molimal symptoms such as breast tenderness, acne, food cravings, and mood changes. Ovulatory cycles are more likely to be associated with dysmenorrhea, although severe dysmenorrhea may suggest endometriosis.

Basal body temperature (BBT) charting has long been used to identify ovulation. This test requires that a woman's morning oral temperature be graphically charted (Fig. 20-5). Oral temperatures are usually 97.0° to 98.0°F during the follicular phase. A postovulatory rise in progesterone levels increases basal temperature by approximately 0.4° to 0.8°F. This *biphasic* temperature pattern is strongly predictive of ovulation (Bates, 1990). Nevertheless, although this test has the advantage of being inexpensive, it is insensitive in many women. Furthermore, for a couple wishing to conceive, the temperature rise follows ovulation, and therefore the window of maximal fertility has been missed (Luciano, 1990). Although this method is discussed here for completeness, most patients are better served by sensitive urinary ovulation detection kits, described next.

Ovulation Predictor Kits

These kits measure urinary luteinizing hormone (LH) concentration by colorimetric assay. They are widely available in pharmacies, are relatively easy to use, and provide clear instructions regarding interpretation. In general, a woman begins testing 2 to 3 days prior to the predicted LH surge, and testing is continued daily. No clear consensus guides the optimal time of day to test. Some specialists suggest that the concentrated first morning void is a logical time. Others are concerned that this sample may provide a false-positive result and recommend testing the second morning urine. Other clinicians reason that the serum LH peak occurs in the morning and that the greatest likelihood of detecting a urinary peak would be in the late afternoon or evening. Because the LH surge spans 48 to 50 hours, timing is probably not critical as long as the test is performed daily. In most instances, ovulation will occur the day following the urinary LH peak (Luciano, 1990; Miller, 1996).

If equivocal results are obtained, the test can be repeated in 12 hours. In one study, urine LH surge assays were estimated to have 100-percent sensitivity and 96-percent accuracy, although this is undoubtedly an overestimate of typical-use results (Grinsted, 1989; Guermandi, 2001).

Serum Progesterone

Adequate progesterone levels are required for endometrial preparation prior to implantation. This has led to the concept of *luteal phase defect (LPD)*, defined as inadequate endometrial development due to suboptimal progesterone production.

Midluteal phase serum progesterone levels have long been used to document ovulation, although the sensitivity of this test has been questioned. In a classic 28-day cycle, serum is obtained on cycle day number 21 following the first day of menstrual bleeding, or 7 days following ovulation. Levels during the follicular phase are generally <2 ng/mL. Values above

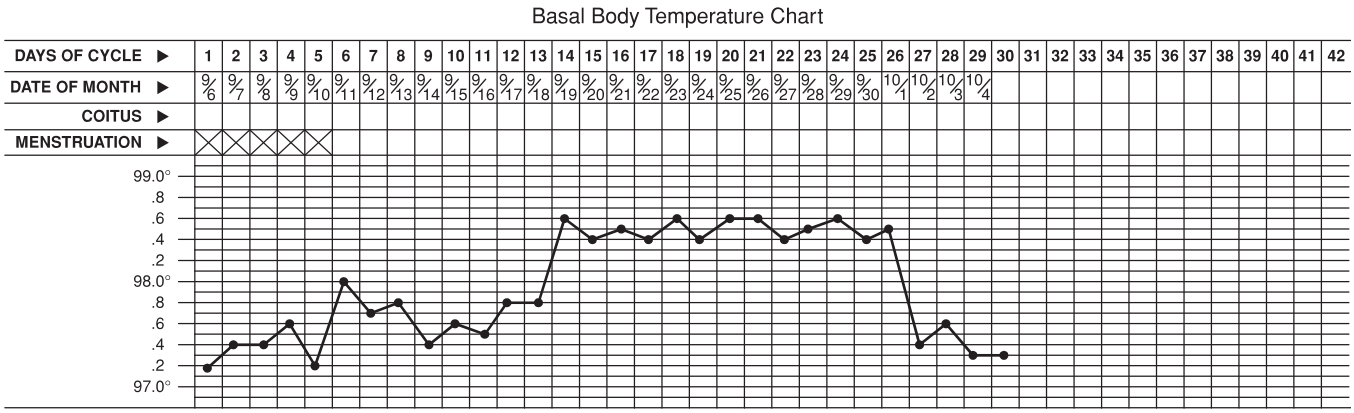

FIGURE 20-5 Biphasic pattern seen on this basal body temperature chart suggests ovulation. (Redrawn with permission from Chang, 2005.)

4 to 6 ng/mL correlate with ovulation and progesterone production by the corpus luteum (Guermandi, 2001). Progesterone is secreted as pulses, and therefore a single measurement does not indicate overall production during the luteal phase. As a result, an absolute threshold for acceptable progesterone levels has not been established. Although some clinicians empirically treat any woman with a progesterone level below approximately 10 ng/mL, the utility of this approach is unproven and is costly. Accordingly, the midluteal progesterone level is best regarded as an acceptable test for ovulation but not an absolute indicator of adequate luteal function.

Endometrial Biopsy

Luteal phase endometrial biopsy was hoped to reflect both corpus luteum function and endometrial response, and thereby provide more clinically relevant information than a serum progesterone level alone (Noyes, 1975). Unfortunately, the utility of this test is severely hampered by high intraobserver and interobserver variability during histologic evaluation (Balasch, 1992; Scott, 1993). An out-of-phase biopsy is found nearly as frequently in fertile as in infertile women, and the overlap in incidence between the two groups is large (Balasch, 1992; Scott, 1993). In its current form, the endometrial biopsy is no longer considered a routine part of infertility evaluation.

Interestingly, the timing of protein expression in the endometrial glands and stroma is being defined. Potential markers for uterine receptivity include osteopontin, cytokines, cell adhesion molecules, ion channels, and the L-selectin ligand, which has been proposed to mediate embryo attachment (Carson, 2002; Garrido-Gomez, 2014; Kao, 2003; Lessey, 1998; Petracco, 2012; Ruan, 2014). In the future, endometrial biopsy or endometrial fluid aspirates may again become part of the diagnostic evaluation if expression patterns of these proteins can predict endometrial receptivity.

Sonography

Serial ovarian sonographic evaluations can demonstrate the development of a mature antral follicle and its subsequent collapse during ovulation. This approach is time consuming, and ovulation can be missed. However, sonography is an excellent approach for supporting the diagnosis of PCOS.

EVALUATION FOR DIMINISHED OVARIAN RESERVE

Ovulatory status does not provide a complete picture of ovarian function. A woman may have regular, ovulatory menses but have reduced follicular response to ovarian stimulation compared with other women of similar age due to a smaller ovarian follicle pool. In this situation, the woman is said to have decreased or diminished ovarian reserve (DOR) and, in more severe presentations, primary ovarian insufficiency (POI). Although most often the result of advancing age, a small ovarian reserve can be linked to smoking, to genetic conditions, or to prior ovarian surgery, chemotherapy, or pelvic irradiation. A more complete discussion of accelerated follicular loss is found in Chapter 17 (p. 377).

TABLE 20-7. Female Aging and Infertility

Female Age (years)	Infertility
20–29	8.0%
30–34	14.6%
35–39	21.9%
40–44	28.7%

Reproductive Aging

Female age and fertility have a clear inverse relationship (Table 20-7) (American Society for Reproductive Medicine, 2014a). This loss is primarily attributable to a decline in oocyte quality and quantity, although accumulating risk for the development of medical disorders or uterine and pelvic abnormalities also contributes. A classic study was performed in the Hutterites, a community that eschews contraception. After ages 34, 40, and 45, the incidence of infertility was 11 percent, 33 percent, and 87 percent, respectively. The average age at last pregnancy was 40.9 years (Menken, 1986; Tietze, 1957). Another study evaluated cumulative pregnancy rates in women using donor insemination. In women younger than 31 years, 74 percent achieved pregnancy within 1 year. These rates fell to 62 percent for women between 31 and 35 years, and further declined to 54 percent in women older than 35 (Treloar, 1998).

Ongoing atresia of nondominant follicles proceeds throughout a woman's reproductive life span. In addition to declining follicular numbers, the risks of genetic abnormalities and mitochondrial deletions in the remaining oocytes substantially rise as a woman ages (Keefe, 1995; Pellestor, 2003). These factors result in lower pregnancy rates and higher miscarriage rates in both spontaneous and stimulated cycles. The overall miscarriage risk in women older than 40 years is estimated to be 50 to 75 percent (Maroulis, 1991).

The follicular loss rate and age at menopause varies between women and is likely genetically determined. For example, a family history of early menopause is correlated with a greater risk of early menopause in an individual woman. However, in most cases, it is impossible to predict the onset of menopause. Therefore, fertility testing is ideally performed starting at age 35 in all patients desiring conception. Testing is also seriously considered in any woman with an unexplained change in menstrual cyclicity, family history of early menopause, or risk factor for POI.

An array of tests has been developed to assess ovarian reserve (American Society for Reproductive, 2015g). Unfortunately, these lack sensitivity and positive predictive value for DOR, particularly if applied to patients at low risk for this process. In addition, these tests are more accurate as predictors of ovarian response to pharmacologic stimulation than as predictors of subsequent pregnancy. The optimal combination of tests and their interpretation continues to be refined. Currently, early follicular measurement of follicle-stimulating hormone (FSH) is probably the most cost-effective approach for the general practitioner. The addition of a serum antimüllerian hormone level is rapidly moving into standard practice, and this hormone is discussed subsequently. Measuring serum inhibin B

levels and the clomiphene citrate challenge test have fallen out of favor.

Abnormal test findings correlate with a poorer prognosis for achieving pregnancy, and referral to an infertility specialist is advisable. Conversely, a normal test result does not negate the effect of a woman's age on her fertility status. This information may be useful in counseling a couple regarding prognosis. Poor results in an older woman can supply an impetus either to attempt donor oocyte in vitro fertilization (IVF) or to pursue alternatives such as adoption. Borderline results in a younger woman with infertility may suggest a need for more intensive treatment. However, caution is advised in using any of these tests as an impetus for immediate treatment with oocyte cryopreservation, IVF, or other treatment in the otherwise asymptomatic patient.

Follicle-Stimulating Hormone and Estradiol

Frequently termed a "cycle day 3" FSH, this may reasonably be drawn between days 2 and 4 following menses onset. With declining ovarian function, the support cells (granulosa cells and luteal cells) secrete less inhibin, a peptide hormone that is responsible for inhibiting FSH secretion by the anterior pituitary gonadotropes (Chap. 16, p. 353). With loss of luteal inhibin, FSH levels rise in the early follicular phase. A value >10 mIU/mL may indicate significant loss of ovarian reserve and prompt more complete evaluation.

The simultaneous measurement of an estradiol level has been thought to lower the incidence of false-negative results in FSH values alone (Buyalos, 1997). Somewhat paradoxically, despite the overall depletion of ovarian follicles, estrogen levels in older women are elevated early in the cycle due to greater stimulation of ovarian steroidogenesis by elevated FSH levels. A cycle-day-3 estradiol level >80 pg/mL is considered abnormal. However, paired FSH and estradiol measurement is no longer recommended for ovarian reserve evaluation because estradiol provides limited additional information compared with FSH testing alone (American Society for Reproductive Medicine, 2015g).

Antimüllerian Hormone

This is the most recent circulating factor to be analyzed as an ovarian reserve predictor (La Marca, 2009). As suggested by its name, antimüllerian hormone (AMH) is expressed by the fetal testes during male differentiation to prevent development of the müllerian system (fallopian tubes, uterus, and upper vagina) (Chap. 19, p. 408). AMH is also expressed by the granulosa cells of small preantral follicles but has limited expression in larger follicles. This suggests that AMH plays a role in dominant follicle recruitment.

Measurement of AMH levels has advantages compared with FSH and inhibin testing. First, AMH expression is gonadotropin-independent and therefore is relatively independent of cycle stage and is consistent across cycles. Second, studies suggest that AMH levels correlate with ovarian primordial follicle number more strongly than FSH or inhibin levels (Hansen, 2011). Furthermore, AMH levels may drop prior to observable changes in FSH or estradiol levels, thereby providing an earlier marker of waning ovarian function. Seifer and associates (2011) reported a steady decline in AMH serum levels across the reproductive life span. The median level approximated 3 ng/mL at age 25, and this dropped to 1 ng/mL at age 35 to 37. Of note, reference levels for FSH, estradiol, and AMH can vary between laboratories. Thus, every clinician should be familiar with their own laboratory's normal values.

Interestingly, AMH levels are under consideration as a tool for diagnosis of PCOS. Levels are raised two- to threefold in affected women compared with normal cycling women (Dumont, 2018; Hornburg, 2014). This observation is consistent with the multiple early follicles found in patients with PCOS.

Antral Follicle Count

Sonographic evaluation of the follicular phase antral follicle count (AFC) is commonly used as a reliable predictor for subsequent response to ovulation induction (Frattarelli, 2000; Maseelall, 2009). The number of small antral follicles reflects the size of the resting follicular pool. Antral follicles between 2 and 100 mm are counted in both ovaries. The total AFC usually ranges between 10 and 20 in a reproductive-aged woman. An AFC with <3 to 6 total antral follicles predicts poor response to gonadotropin stimulation during IVF cycles, but this measure is limited by low sensitivity.

EVALUATION FOR FEMALE ANATOMIC ABNORMALITIES

Tubal and Pelvic Factors

Symptoms such as chronic pelvic pain or dysmenorrhea may suggest tubal obstruction, pelvic adhesions, or both. Adhesions can prevent normal tubal movement, ovum pick-up, and transport of the fertilized egg into the uterus. Etiologies include tubal disease, especially pelvic infection; endometriosis; and prior pelvic surgery.

Of these causes, approximately one third to one fourth of all infertile women are diagnosed with tubal disease in developed countries. In the United States, the most common cause of tubal disease is infection with *C trachomatis* or *N gonorrhoeae.* With PID, tubal infertility has been estimated to follow in 12 percent, 23 percent, and 54 percent of women following one, two, or three cases of PID, respectively (Lalos, 1988). Nevertheless, an absent PID history is not overly reassuring, as nearly one half of patients who have tubal damage have no clinical history of antecedent disease (Rosenfeld, 1983).

In contrast, in developing countries, genital tuberculosis may account for 3 to 5 percent of infertility cases (Aliyu, 2004; Nezar, 2009). As a result, this diagnosis is considered in immigrant populations from countries with endemic infection. In these cases, tubal damage and endometrial adhesions are underlying causes. Genital tuberculosis typically follows hematogenous seeding of the reproductive tract from an extragenital primary infection. The likelihood of a return to fertility after antitubercular treatment is low, and IVF with embryo transfer remains the most reliable approach (Aliyu, 2004).

With endometriosis, chronic inflammation and intraperitoneal bleeding can lead to pelvic adhesions. Endometriosis is also

thought to diminish fertility by an increase in peritoneal fluid inflammatory factors, alterations in endometrial immunologic function, poor oocyte or embryonic quality, or impaired implantation (American Society for Reproductive Medicine, 2012).

Salpingitis isthmica nodosa is an inflammatory condition of the fallopian tube, characterized by nodular thickening of its isthmic portion. Histologically, smooth muscle proliferation and diverticula of tubal epithelium contribute to this thickening. This uncommon condition typically develops bilaterally and progressively leads to ultimate tubal occlusion and infertility (Saracoglu, 1992). Treatment options include those for proximal tubal occlusion as discussed in Chapter 21 (p. 459).

Of note, a prior ectopic pregnancy, even if treated medically with methotrexate, implies the likelihood of significant tubal damage. Residual adhesions are common after even the most meticulous pelvic surgery. This is particularly true in cases with pelvic inflammation, due to blood, infection, or irritation caused by mature cystic teratoma (dermoid) contents.

Uterine Abnormalities

Uterine abnormalities can be either congenital or acquired. Common congenital anomalies include uterine septum, bicornuate uterus, unicornuate uterus, and uterine didelphys. With the possible exception of a large uterine septum, the fertility effects of these anomalies have been difficult to verify, although a subset are clearly associated with pregnancy complications. As a uterine septum can now be removed relatively simply and safely with hysteroscopy, most infertility specialists will proceed with surgery if this anomaly is identified. Clinical findings and management of congenital reproductive tract anomalies are fully described in Chapter 19 (p. 421).

Acquired anomalies include intrauterine leiomyomas, adenomyosis, polyps, and Asherman syndrome. Leiomyomas may diminish fertility by proposed mechanisms that include endometrial cavity distortion with associated changes in blood flow and endometrial maturation; endometrial inflammation; disordered uterine contractility that may hinder sperm or embryo transport; obstruction of the proximal fallopian tubes; or interference with ovum capture (American Society for Reproductive Medicine, 2017a; Makker, 2013; Metwally, 2012; Pritts, 2001; Samejima, 2014). Thus far, no algorithm incorporating tumor number, volume, or location accurately predicts the need to remove them, either to improve implantation rates or to lower pregnancy complications. Namely, miscarriage, placental abruption, and preterm labor are potential problems. Nevertheless, although not supported by definitive evidence, most experts suggest removal of submucosal fibroids that significantly distort the endometrial cavity. In addition, many consider surgical excision of leiomyomas larger than 4 to 5 cm or multiple smaller tumors in this range regardless of location. Importantly, surgical benefits are weighed against postoperative complications that lower subsequent fertility. These include pelvic adhesion formation, creation of Asherman syndrome following large submucous leiomyoma removal, or the need for cesarean delivery if the full myometrial thickness is transected.

The incidence of adenomyosis in the infertility population is unknown. However, improvements in imaging strongly suggest that it occurs at earlier ages than previously appreciated. Adenomyosis is thought to impact fertility and obstetric outcomes via functional and structural defects in the endometrium and myometrium (Buggio, 2018).

Endometrial polyps are found in an estimated 3 to 5 percent of infertile women (Farhi, 1995; Soares, 2000). The prevalence is higher in women with symptoms such as intermenstrual or postcoital bleeding. Although these complaints typically prompt hysteroscopic removal, most data have not clearly demonstrated an indication for removing polyps in otherwise asymptomatic women without risks for endometrial cancer (Ben-Arie, 2004; DeWaay, 2002; Jayaprakasan, 2014). Of note, however, one study suggested that removal of even small polyps (<1 cm) may improve pregnancy rates following intrauterine insemination (Perez-Medina, 2005).

The presence of intrauterine adhesions, also called *synechiae*, is termed *Asherman syndrome*. This diagnosis is discussed in Chapter 17 (p. 374). Asherman syndrome develops most frequently in women with prior uterine dilation and curettage, particularly in the context of infection and pregnancy (Schenker, 1996). The clinical history will often include an acute postsurgical decline in menstrual bleeding or even amenorrhea. A woman with an intrauterine device complicated by infection or a woman with genital tuberculosis is also at high risk for intrauterine adhesions. Treatment of Asherman syndrome involves hysteroscopic lysis of the scar tissue as described in Chapter 21 (p. 461) and Chapter 44 (p. 1069).

Anatomy Evaluation

Several approaches for evaluating pelvic anatomy are: (1) hysterosalpingography (HSG), (2) transvaginal sonography (TVS) with or without saline instillation, (3) 3-dimensional (3-D) TVS, (4) hysteroscopy, (5) laparoscopy, and (6) magnetic resonance (MR) imaging. As shown in Table 20-8, each has its own advantages and disadvantages.

Hysterosalpingography

This radiographic tool can display the shape and size of the uterine cavity and define tubal status. HSG is generally performed on cycle days 5 through 10. At this time, few intrauterine clots should remain to block tubal outflow or give the false impression of an intrauterine abnormality. Furthermore, a woman theoretically has not ovulated or possibly conceived. For this test, iodinated contrast medium is infused through a catheter placed into the uterus. With fluoroscopy, dye is followed as it fills the uterine cavity, then the tubal lumen, and finally spills out of the tubal fimbria into the pelvic cavity (Fig. 20-6).

In a large metaanalysis, HSG was demonstrated to have 65-percent sensitivity and 83-percent specificity for tubal obstruction (Swart, 1995). Tubal contractions, particularly cornual spasm, can give the incorrect impression of proximal fallopian tube obstruction (a false-positive result). A false-negative result is much less common. Many causes of tubal disease affect both tubes, and thus unilateral disease is unusual. Unilateral obstruction with a normal contralateral tube most likely reflects dye following the path of least resistance during the HSG procedure. However, laparoscopy with chromotubation is considered prior to treatment to confirm a final diagnosis.

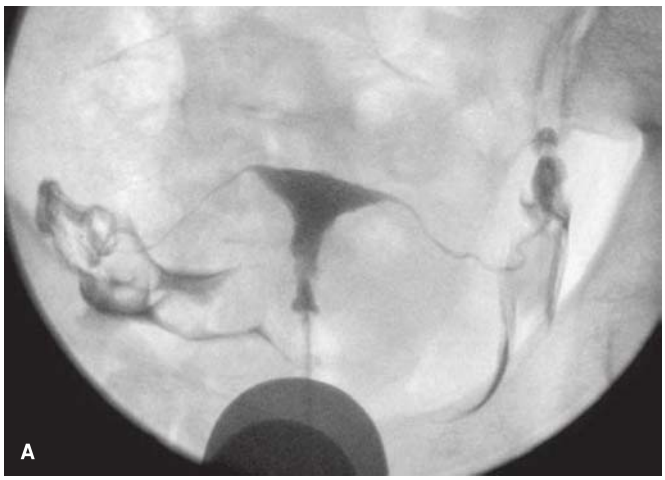
TABLE 20-8. Advantages and Disadvantages of Various Methods for Evaluating Pelvic Anatomy

	Tubal Patency	Uterine Cavity	Developmental Defects	Endometriosis or PAD	Ovaries
HSG	+	+	–	+/–	–
TVS	–	+/–	+/–	–	+
3-D TVS	–	+	+	–	+
SIS	–	+	+	–	+
MR imaging	–	+	+	+ (endometrioma)	+
Hysteroscopy	–	+	+ (with laparoscopy)	–	–
Laparoscopy	+	–	+ (with hysteroscopy)	+	+

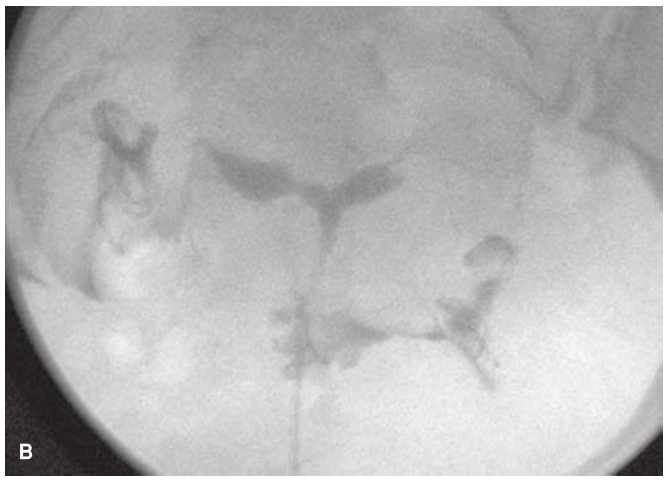
HSG = hysterosalpingography; MR = magnetic resonance; PAD = pelvic adhesive disease; SIS = saline-infusion sonography; TVS = transvaginal sonography.

HSG is not reliable in detecting peritubal or pelvic adhesions, although loculations of dye around the tubes may be suggestive. Thus, HSG is an excellent predictor of tubal patency but is less effective at predicting normal tubal function or pelvic adhesions. Pregnancy rates can rise after HSG and are thought to follow flushing of intratubal debris. Recent studies suggest that subsequent spontaneous pregnancy rates may be greater following oil-based dyes rather than water-based ones. Nevertheless, water-based dyes currently remain the preference in most practices as these generally carry a lower allergic reaction risk (Dreyer, 2017).

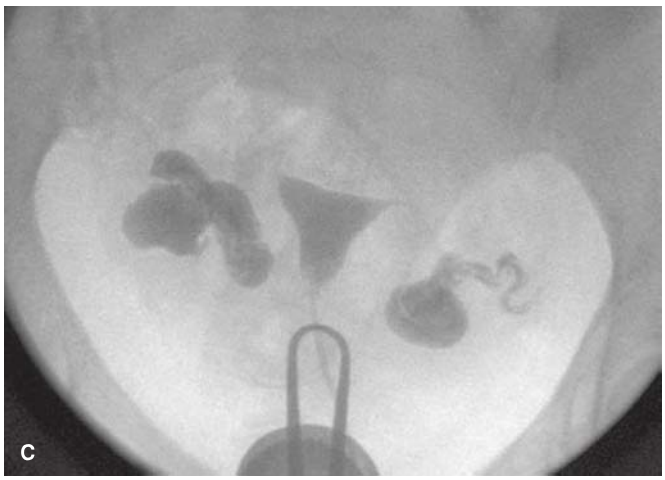
HSG also provides analysis of the intrauterine cavity contour. A polyp, leiomyoma, or adhesion within the cavity will block dye diffusion and create an intrauterine "defect" in dye



Normal



Asherman syndrome



Bilateral hydrosalpinges

FIGURE 20-6 Hysterosalpingogram findings. These images are digitally reversed, causing the radiopaque contrast to appear black against a radiolucent background. **A.** Normal hysterosalpingogram. Radiopaque dye fills the uterine cavity and spills from both fallopian tubes into the peritoneal cavity. The dye catheter is seen beneath the endometrial contour. **B.** Asherman syndrome. Contrast dye fills a small and irregularly shaped endometrial cavity, often described as having a "moth-eaten" appearance. **C.** Bilateral hydrosalpinges. Note the marked tubal dilation and lack of spill of contrast medium at the fimbrial ends. (Reproduced with permission from Dr. Kevin Doody.)

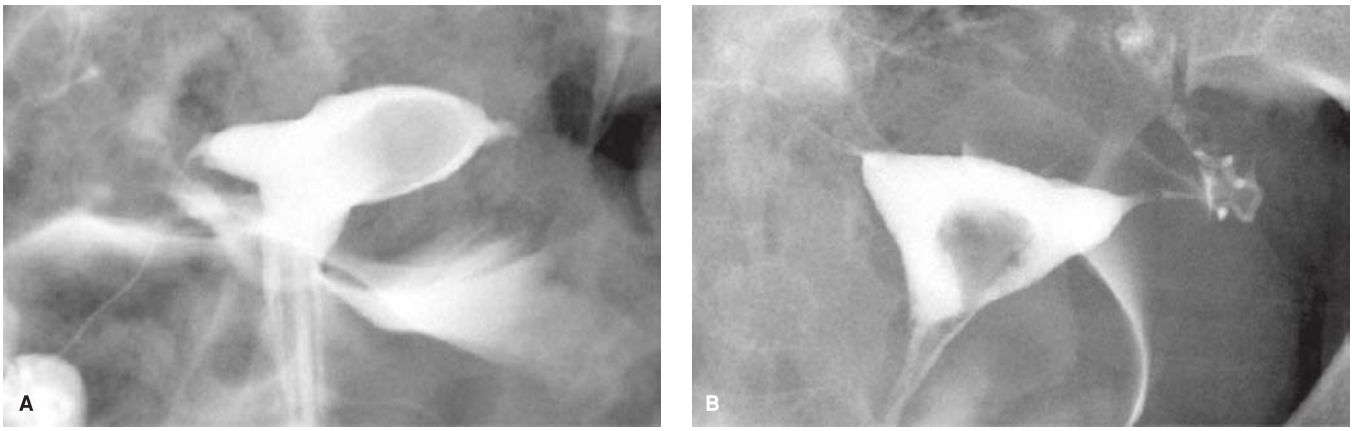


FIGURE 20-7 Appearance of leiomyoma and endometrial polyps on hysterosalpingogram (HSG). **A.** A broad-based filling defect is formed during HSG by a submucous leiomyoma. Note distortion of the left cornu by this mass. **B.** A more irregular filling defect is created by an endometrial polyp. Note that polyps generally have a less substantial attachment to the myometrium. (Reproduced with permission from Dr. Diane Twickler.)

opacity on the radiograph (Fig. 20-7). Although false-positive results may originate from blood clots, mucus plugs, or shearing of the endometrium during placement of the intrauterine catheter, HSG accurately identifies intrauterine pathology. In one study of more than 300 women in which hysteroscopy was the gold standard, HSG was determined to be 98-percent sensitive and 35-percent specific and have a positive predictive value of 70 percent and a negative predictive value of 8 percent. Most misdiagnoses were due to an inability to distinguish polyps from submucous leiomyomas. Other studies have reported much less impressive results. For example, Soares and coworkers (2000) reported sensitivity and positive predictive values of only 50 and 30 percent, respectively, for endometrial polyp and submucous leiomyoma detection in asymptomatic patients. Nevertheless, HSG is a valuable tool for initial uterine cavity evaluation.

HSG can also define developmental uterine anomalies (Fig. 20-8). A Y-shaped uterus identified during HSG may represent either a uterine septum or bicornuate uterus. In these cases, the external contour of the uterine fundus must be evaluated using MR imaging, high-resolution sonography, 3-D TVS, or laparoscopy. With a uterine septum, a smooth fundal contour is found, whereas with a bicornuate uterus, a cleft between the two uterine horns is seen. This is an important distinction, as a septum is often resected, but a bicornuate uterus is usually not treated. In general, uterine anomalies do not cause infertility but may be associated with miscarriage, malpresentation, or preterm birth. Accordingly, it may be reasonable to surgically treat a uterine anomaly to improve pregnancy outcome. However, a couple is carefully counseled that the conception rate itself is unlikely to be affected. Fertility effects of congenital anomalies are further discussed in Chapter 19 (p. 422).

Sonography

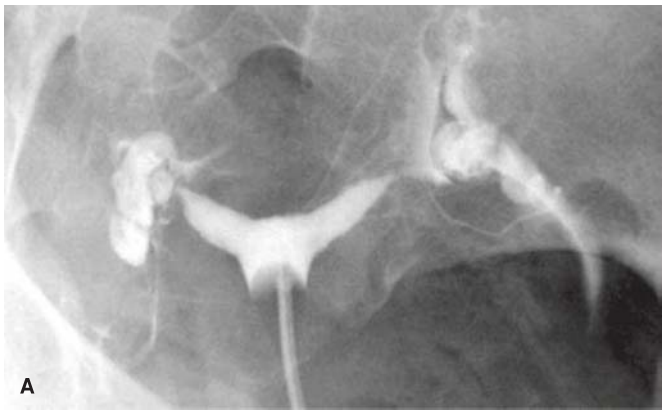
TVS may be helpful in determining uterine anatomy, particularly during the luteal phase, when the thickened endometrium acts as contrast to the myometrium. Now more widely available, 3-D sonography is advancing discriminatory abilities and decreasing the need for MR imaging to define uterine anatomy (Chap. 2, p. 41).

Infusion of saline into the endometrial cavity during sonography performed in the follicular phase provides another approach to create contrast between the cavity and uterine walls. This procedure has many names including hysterosonography, sonohysterography, or saline-infusion sonography (SIS). Details of this procedure are described in Chapter 2 (p. 31). SIS has a reported sensitivity of 75 percent and specificity of more than 90 percent for detecting endometrial defects. It has an acceptable positive predictive value of 50 percent and an excellent negative predictive value of 95 percent, which greatly exceeds the negative predictive value of HSG (Grimbizis, 2010; Seshadri, 2015; Soares, 2000). Moreover, SIS may be more sensitive than HSG in determining whether a cavitary defect is a pedunculated leiomyoma or a polyp (Figs. 8-5 and 9-4, pp. 186 and 206). Perhaps more importantly, SIS can help determine what portion of a submucous leiomyoma is within the cavity. Importantly, only those with less than a 50-percent intramural component are considered for hysteroscopic resection.

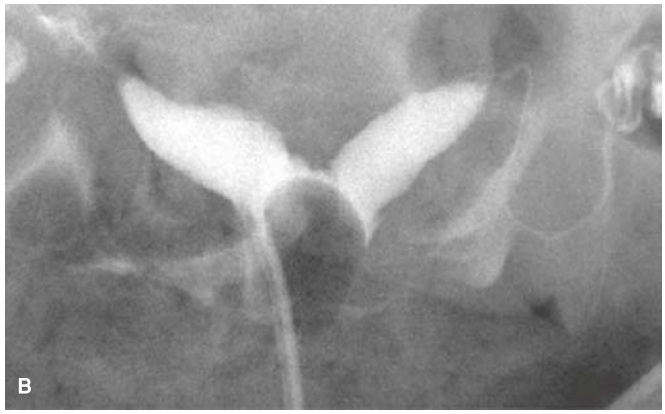
The primary limitation of standard SIS is that it does not provide information regarding the fallopian tubes, although rapid loss of saline into the pelvis is certainly consistent with at least unilateral patency. SIS is generally less painful than HSG and does not require radiation exposure. Thus, if information about tubal patency is not required, SIS is typically preferred. Notably, several radiologists are currently introducing air or contrast into the uterus during sonography. This permits evaluation of tubal patency and may be a broadly available alternative in the future (Groszmann, 2016).

Laparoscopy

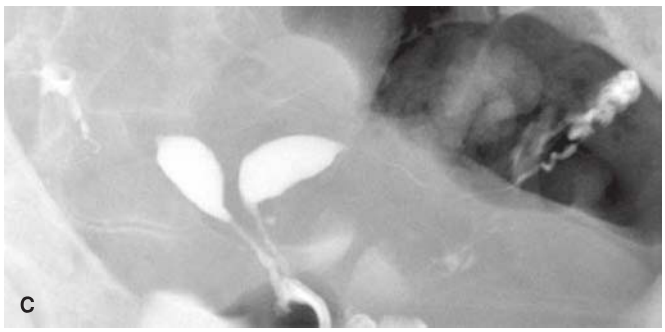
Direct inspection provides the most accurate assessment of pelvic pathology, and laparoscopy is the gold standard approach. Chromotubation may be performed, and a dilute dye is injected through an acorn cannula placed against the cervix or through a balloon catheter positioned within the uterine cavity. Tubal



Bicornuate uterus



Septate uterus



Uterine didelphys

FIGURE 20-8 Hysterosalpingogram appearance of müllerian developmental anomalies. **A.** Bicornuate uterus, due to a failure of fusion of the müllerian ducts, produces a fundal defect with wide-spaced uterine horns. **B.** Septate uterus due to a failure of resorption. This moderate septum displaces the radiopaque dye to the level of the radiolucent injector balloon. **C.** Uterine didelphys consisting of two completely separate müllerian systems including duplication of the cervix. spill is evaluated through the laparoscope (Fig. 20-9). Methylene blue is commonly used. However, methylene blue rarely may induce acute methemoglobinemia, particularly in patients with glucose-6-phosphate dehydrogenase deficiency. One 1-mL vial of methylene blue is mixed with 50 to 100 mL of sterile saline for injection through the cervical cannula. Laparoscopy allows both diagnosis and immediate surgical treatment of abnormalities such as endometriosis or pelvic adhesions.

As laparoscopy is an invasive procedure, it is not advocated in place of HSG as part of the initial infertility evaluation. Exceptions include women with a history or symptoms suggestive of endometriosis or prior pelvic inflammation. However, even in these women, a preliminary HSG may be informative (De Hondt, 2005).

If laparoscopy is clearly indicated, then hysteroscopy can also be performed to evaluate the uterine cavity. Moreover, in operative hysteroscopic cases, laparoscopy can help direct surgery and avoid perforation, for example, during septal incision.

Laparoscopy may be also considered in patients who fail to conceive with oral or gonadotropin ovulation induction. If pelvic disease is found and treated, progression to IVF may be avoided. With improvements in IVF success rates, this latter argument is becoming less justifiable, as the cost of surgery well exceeds the cost of an IVF cycle.

Hysteroscopy

Endoscopic evaluation of the intrauterine cavity is the preferred method to define intrauterine abnormalities. Hysteroscopy can be performed in an office or operating room. With improved instrumentation, the ability to concurrently diagnose and treat abnormalities in the office is growing. However, substantially more extensive hysteroscopic surgery is possible in the operating room.

Cervical Factors

The cervical glands secrete mucus that is normally thick and impervious to sperm and ascending infections. High estrogen

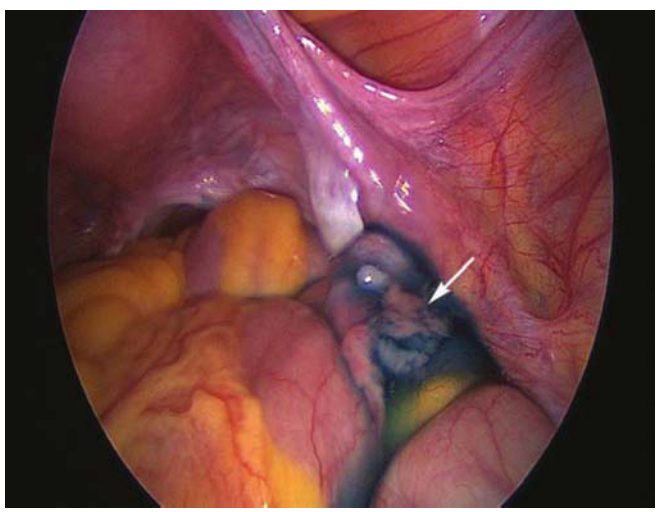

FIGURE 20-9 Chromotubation seen at laparoscopy. Note the spill of blue dye from the fimbriated end of the fallopian tube onto the ovarian surface. (Reproduced with permission from Dr. Kevin Doody.)

levels at midcycle induce mucus to become thin and stretchy and to have a higher sodium chloride concentration. Estrogen-primed cervical mucus filters out nonsperm components of semen and forms channels that help direct sperm into the uterus. Midcycle mucus also creates a reservoir for sperm. This allows ongoing release during the next 24 to 72 hours and extends the potential time for fertilization (Katz, 1997).

Abnormalities in mucus production are most frequently observed in women who have undergone cryosurgery, cervical conization, or a loop electrosurgical excision procedure (LEEP) for treatment of cervical neoplasia. Cervical infection may also worsen mucus quality, but data are conflicting. Implicated agents include *C trachomatis*, *N gonorrhoeae*, *Ureaplasma urealyticum*, and *Mycoplasma hominis* (Cimino, 1993).

The postcoital test, also known as the Sims-Huhner test, has been used historically to evaluate cervical mucus. A couple is requested to have intercourse on the day of ovulation, and a sample of the cervical mucus is evaluated for elasticity (*Spinnbarkeit*) and for the number of motile sperm per high-power field. This test has been hampered by a limited consensus on the definition of a normal test (Oei, 1995). Moreover, in a randomized trial, a normal postcoital test did not predict greater cumulative pregnancy rates (Oei, 1998).

Many infertility specialists recommend bypassing the cervix with intrauterine insemination (IUI) in any woman with prior cervical surgery, especially if she has noted a decline in midcycle mucus production. The remaining utility of the postcoital test is for the rare couple who will not consider IUI or who do not have IUI readily available. In regions in which more specific testing cannot be obtained, a postcoital test will provide basic information regarding mucus production, appropriate intercourse practices, and presence of motile sperm.

EVALUATION OF MALE INFERTILITY

Causes of male infertility can roughly be categorized as abnormalities of sperm production, sperm function, or obstruction of the ductal outflow tract. Normal sexual function with appropriate deposition of sperm during intercourse is also required (American Society for Reproductive Medicine, 2015c, 2018d).

Normal Spermatogenesis

Analogous to the ovary, testes have two functions: the generation of mature germ cells (sperm) and the production of male hormones, primarily testosterone. The seminiferous tubules contain developing sperm and support cells called *Sertoli cells* or *sustentacular cells* (see Fig. 20-3). The Sertoli cells form tight junctions that produce a blood-testis barrier. This avascular space within the seminiferous tubules protects sperm from antibodies and toxins but also makes these cells dependent on diffusion for oxygen, nutrients, and metabolic precursors. Located between the seminiferous tubules are Leydig cells, also called *interstitial cells*, which are responsible for steroid hormone production. In simplistic terms, Leydig cells are similar to the theca cells of the ovary.

Unlike the ovary, testes contain stem cells that allow ongoing production of mature germ cells throughout a male's life. In a fertile male, approximately 100 to 200 million sperm are produced each day (Sigman, 1997). The process begins with a diploid (46,XY) spermatogonial cell and results in four mature sperm with a haploid (23,X or 23,Y) karyotype (see Fig. 20-3). During this developmental process, most sperm cytoplasm is lost, mitochondria that provide energy are positioned in the sperm midpiece, and sperm flagella develop.

Production of sperm requires approximately 70 days. An additional 12 to 21 days is needed for sperm to be transported into the epididymis. Here, they further mature and develop motility (Heller, 1963; Hinrichsen, 1980; Rowley, 1970). Importantly, due to this prolonged developmental period, the results of a semen analysis reflect events during the past 3 months, not a single point in time.

To fertilize an oocyte, human sperm must undergo a process known as *capacitation*. Capacitation results in sperm hyperactivation and the ability to release acrosomal contents, which allow penetration of the ovum's zona pellucida.

High local levels of testosterone are integral to normal spermatogenesis. LH from the anterior pituitary gland stimulates production of testosterone by the Leydig cells. FSH increases LH receptor density on the Leydig cells, thus indirectly contributing to testosterone production. In addition, FSH elevates production of sex hormone–binding globulin, also called *androgen-binding protein*. Androgen-binding protein binds testosterone and maintains high concentrations of this hormone in the seminiferous tubules (Sigman, 1997).

In addition to hormone levels, testicular volume often reflects spermatogenesis, and a normal volume is between 15 and 25 mL. Most of this volume is provided by the seminiferous tubules. Thus, a small testicular volume is a strong indicator of abnormal spermatogenesis.

Spermatogenesis is directed by genes on the Y chromosome. Autosomal genes also provide important contributions, which continue to be elucidated. Therefore, genetic abnormalities may adversely affect this process, as discussed later (p. 445).

Male fertility likely diminishes modestly with aging. Pregnancy rates decline and time to conception lengthens. Studies of semen parameters across age suggest that sperm concentration is maintained, however, sperm motility and morphology progressively worsen (Levitas, 2007). The clinical significance of these changes is unclear (Kidd, 2001). Outside of semen parameters, the higher incidence of erectile and other sexual dysfunction with male aging undoubtedly contributes to lower conception rates. Data also suggest that paternal age may negatively affect reproductive outcomes in both natural and assisted pregnancies (Mazur, 2018). In sum, although advancing male age may lower fertility, it is probably insignificant compared with aging changes in women.

Semen Analysis

Collection

This is a core test in male fertility evaluation. For this test, the male is asked to refrain from ejaculation for 2 to 3 days, and a specimen is collected by masturbation into a sterile cup. A proposed period of abstinence is based on the belief that this will result in a more accurate result, although this may not be true

for all semen parameters (Hanson, 2018a). If masturbation is not an option, then a couple can use specially designed Silastic condoms without lubricants. Importantly, the sample should arrive in the laboratory within an hour of ejaculation to allow for optimal analysis.

The sample undergoes liquefaction, or thinning of the seminal fluid, due to enzymes from the liquid contribution of the prostate gland. This process takes 5 to 20 minutes and allows more accurate evaluation of the sperm contained in the seminal fluid. Ideally, two semen samples separated by at least a month are analyzed. In practice, frequently only a single sample is analyzed if parameters are normal.

Semen Analysis Results

The reference values for the semen analysis and frequently used terms are shown in Tables 20-9 and 20-10. Notably, semen characteristics vary across time in a single individual. Also, semen analysis results, particularly morphologic interpretation, may differ between laboratories. Thus, reference ranges for the laboratory being used should be known. Although total motile sperm count correlates with fertility, not all males with "normal" semen parameters display normal fertility (Guzick, 2001). Conversely, patients with semen analysis results outside the reference range may achieve pregnancy. The lack of absolute predictive value for this test is likely due to the fact that it does not provide information regarding sperm function, that is, the ultimate ability to fertilize an oocyte.

Most semen analysis reports will indicate semen volume, pH, and presence or absence of fructose. Nearly 80 percent of semen volume comes from the seminal vesicles. Seminal fluid is alkaline and is thought to protect sperm from acidity in prostatic secretions and in the vagina. Seminal fluid also provides fructose as an energy source for sperm. An acidic pH or lack of fructose is consistent with obstruction of the efferent ductal system (Daudin, 2000).

Low semen volume often simply reflects incomplete specimen collection or short abstinence interval. However, it may indicate partial vas deferens obstruction or retrograde ejaculation. Partial or complete vas deferens obstruction may be caused by infection, tumor, prior testicular or inguinal surgery, or trauma. Retrograde ejaculation follows failed closure of the bladder neck during ejaculation and allows seminal fluid to flow backward into the bladder. Retrograde ejaculation is suspected in men with diabetes mellitus, spinal cord damage, or prior prostate or other retroperitoneal surgery that may have damaged nerves (Hershlag, 1991). Medications, particularly β-blockers, may contribute to this problem. A postejaculatory urinalysis can detect sperm in the bladder and confirm the diagnosis. If urine is properly alkalinized, these sperm are viable and can be retrieved to achieve pregnancy.

Sperm counts may be normal, or males may have low sperm counts (oligospermia) or no sperm (azoospermia) (Sharlip, 2002). Oligospermia is defined as a concentration less than 15 million sperm per milliliter, and counts <5 to 10 million per milliliter are considered severe. The prevalence of azoospermia is approximately 1 percent of all men. Azoospermia may result from outflow tract obstruction, termed *obstructive azoospermia*, such as that which occurs with congenital absence of the vas deferens, severe infection, or vasectomy. Azoospermia may also follow testicular failure (*nonobstructive azoospermia*). In the latter case, careful centrifugation and analysis may identify a small number of motile sperm adequate for IVF use. Alternatively, this latter group may have viable sperm obtainable through either epididymal aspiration or testicular biopsy. As described later, endocrine and genetic evaluation is indicated for men with abnormal sperm counts.

Sperm movement also is assessed, and diminished motility is termed *asthenospermia*. Some laboratories will distinguish between rapid (grade 3 to 4), slow (grade 2), and nonprogressive (grade 0 to 1) movement. *Total progressive motility* is the percentage of sperm exhibiting forward movement (grades 2 to 4). Asthenospermia has been attributed to prolonged abstinence, antisperm antibodies, genital tract infections, or varicocele. To differentiate between dead and nonmotile sperm, a hypoosmotic swelling test can be completed. Unlike dead sperm, living sperm can maintain an osmotic gradient. Thus, when mixed with a hypoosmotic solution, living, nonmotile sperm with normal membrane function swell and coil as fluid is absorbed (Casper, 1996). Once identified, these viable sperm may be used for intracytoplasmic sperm injection.

Abnormal sperm morphology is termed *teratospermia* or *teratozoospermia*. Kruger and associates (1988) developed a detailed

TABLE 20-9. Semen Analysis Terminology

Term[a]	Definition[b]
Oligospermia	Sperm concentration 10–15 million sperm/mL (mild-moderate) or <5–10 million/mL (severe)
Asthenospermia	Greater proportion of immotile sperm or sperm with decreased motility
Teratospermia	Increased proportion of morphologically abnormal sperm
Azoospermia	Semen present but lacks sperm
Aspermia	Sperm and seminal plasma lacking (anejaculation)
Leukocytospermia	Increased white blood cell count
Necrospermia	All sperm nonviable or immotile

[a]Alternative terminology includes oligozoospermia, asthenozoospermia, and teratozoospermia.
[b]As compared with World Health Organization (1999) reference values.

TABLE 20-10. Semen Analysis Reference Limits

Volume	>1.5 mL[a]
Count	>15 million/mL[a]
Total Motility	>40%[a]
Morphology	>4%[a]
WBCs	<1 million/mL[b]
Round cells	<5 million/mL[b]

[a]Data from Cooper, 2010.
[b]Data from World Health Organization, 1999.
WBCs = white blood cells.

characterization of normal sperm morphology, which showed improved correlation with fertilization rates during IVF cycles. Their criteria require careful analysis of the shape and size of the sperm head, the relative size of the acrosome in proportion to the head, and characteristics of the tail. Significantly lower fertilization rates are seen when normal morphology of the sample falls below 4 percent.

Round cells in a sperm sample may represent either leukocytes or immature sperm. White blood cells (WBCs) can be distinguished from immature sperm using various techniques, including a myeloperoxidase stain for WBCs (Wolff, 1995). True leukocytospermia is defined as greater than 1 million WBCs per milliliter and may indicate chronic epididymitis or prostatitis. In this scenario, many andrologists consider empiric antibiotic treatment prior to obtaining a repeat semen analysis. A common protocol would include doxycycline at a dosage of 100 mg orally twice daily for 2 weeks. Alternative approaches include culture of any expressible discharge or of the semen sample.

Unless a general obstetrician-gynecologist has developed expertise in male infertility, persistently abnormal semen analysis findings are an indication for referral to an infertility specialist. Although the partner may be referred directly to a urologist, it may be more reasonable to refer the couple to a reproductive endocrinologist, as the female will also require evaluation. Treatment is likely to be more complex in these couples and will typically be directed to both partners.

DNA Fragmentation

Elevated sperm DNA fragmentation as a cause of male infertility has garnered increased attention (Sakkas, 2010; Zini, 2009). Although some degree of DNA damage is likely repaired during embryogenesis, the location and extent of damage may lower fertilization and raise miscarriage rates. Greater levels of DNA damage are associated with advanced paternal age and external factors such as cigarette smoking, chemotherapy, radiation, environmental toxins, varicocele, and genital tract infections. In sperm samples with abnormal DNA fragmentation rates, higher levels of reactive oxygen species have been observed. In response to this, dietary supplementation with the antioxidants vitamin C and vitamin E has been proposed. However, data are currently lacking regarding the efficacy of this approach.

Numerous tests are currently available to analyze for DNA integrity and include the Sperm Chromatin Structure Assay (SCSA), the terminal deoxynucleotidyl transferase–mediated dUTP nick-end labeling (TUNEL) assay, the single-cell gel electrophoresis assay (COMET), and the sperm chromatin dispersion test (SCD) (American Society for Reproductive Medicine, 2013c). Each of these tests provides semiquantitative data on DNA structure. However, there is a lack of consensus regarding their appropriate threshold values and their ability to predict successful pregnancy. As a result, routine use of these is not recommended.

Additional Sperm Testing

Antisperm antibodies may be detected in as many as 10 percent of men. However, the negative fertility effects of antisperm antibodies found in semen is controversial. These antibodies may be particularly prevalent following vasectomy, testicular torsion, epididymitis, testicular biopsy, or other clinical situations in which the blood-testis barrier is breached (Lotti, 2018). Treatment historically included corticosteroids, but their efficacy to improve fertility is unclear. Moreover, significant side effects can include aseptic necrosis of the hip. Current data suggest that an antisperm antibody assay does not need to be a routine component of an infertility evaluation.

Numerous assays have been developed to test sperm function. These include the mannose fluorescence assay, hemizona assay, sperm penetration assay, and acrosome reaction test. The predictive significance of these assays is questionable, as they are based on nonphysiologic conditions and results vary among infertility centers. Most are no longer used and are not considered part of a basic infertility evaluation.

Hormonal Evaluation

Hormonal testing in the male is analogous to endocrine testing in an anovulatory female. Essentially, abnormalities may be due to central defects in hypothalamic-pituitary function or to defects within the testes. Most urologists will defer testing unless a sperm concentration is below 10 million/mL. Testing will include measurements of serum FSH and testosterone levels, and TSH and prolactin levels are considered.

Low FSH and low testosterone levels are consistent with hypothalamic dysfunction, such as idiopathic hypogonadotropic hypogonadism or Kallmann syndrome (Chap. 17, p. 378). In these patients, sperm production may be achieved with gonadotropin treatment. Although such treatment is frequently successful, at least 6 months may be required for detection of sperm production.

Elevated FSH and low testosterone levels provide evidence of testicular dysfunction, and most men with oligospermia are in this category. For men with this FSH and testosterone level pattern, the value of testosterone replacement should be determined. For example, normal spermatogenesis requires high levels of intratesticular testosterone, which cannot be achieved with exogenous testosterone. Furthermore, many of these men will lack spermatogonial stem cells. Thus, testosterone replacement will not rescue sperm production. In fact, replacement will decrease gonadotropin stimulation of remaining testicular function through negative feedback at the hypothalamus and pituitary. Unless the couple has chosen to use donor sperm, androgen supplementation is deferred during fertility treatment. However, replacement will provide other benefits, such as improved libido and sexual function, maintenance of muscle mass and bone density, and a general sense of well-being.

Imaging

Scrotal sonography is a common approach used to examine testicular morphology and identify varicocele or epididymal cysts or abscesses. Transrectal sonography provides information regarding the prostate and seminal vesicles or more central areas of obstruction in the vas deferens. More recently, MR imaging has become the preferred modality for imaging male accessory sex glands and ducts (Jurewicz, 2016; Mittal, 2017).

Testicular Biopsy

Evaluation of a severely oligospermic or azoospermic male may include either open or percutaneous testicular biopsy to determine whether viable sperm are present in the seminiferous tubules (Sharlip, 2002). For example, even men with testicular failure diagnosed by elevated serum FSH levels may have adequate sperm on biopsy for use in intracytoplasmic sperm injection. The biopsy specimen can be cryopreserved for future extraction of sperm during an IVF cycle. However, freshly biopsied specimens are generally felt to provide higher success rates. Thus, the biopsy may have diagnostic, prognostic, and therapeutic value.

GENETIC SCREENING

Testing before conception is often more straightforward and less stressful for the couple than delaying until pregnancy has been achieved. (American College of Obstetricians and Gynecologists, 2017a,b, 2018). Preconception carrier screening also allows a couple to consider the most complete range of reproductive options. Knowing the risk of having an affected child, a couple may consider preimplantation genetic diagnosis, prenatal genetic testing, or the use of donor gametes. One study demonstrated that indications for genetic screening were overlooked in approximately 25 percent of couples (McClatchey, 2018). To improve pregnancy outcomes, every attempt should be made to avoid this missed opportunity.

Traditional genotyping methods detect a limited number of mutations. These tests have been developed to be specific for the more common mutations found in a given ethnic group or clinical scenario. More recently, the cost of DNA sequencing has been greatly reduced by next-generation sequencing (NGS) techniques (Hallam, 2014). It is now possible to perform whole exome sequencing (WES) or whole genome sequencing (WGS) to obtain a full catalogue of an individual's DNA sequence.

These expanded genotyping panels hold great promise, as they allow rapid and efficient testing of many genes and thousands of mutations concurrently. However, the clinical relevance of numerous detected variants has not been determined. These are called *variants of unknown significance (VUS),* and limited data guide management once variants are identified. Thus, rigorous analytic and clinical validation is required before widespread clinical application of WES or WGS can be recommended (Prior, 2014).

Genetic Screening in the Female

Specific carrier screening is recommended by the American College of Obstetricians and Gynecologists (2017a,b) and by other advocacy groups and societies. No doubt, guidelines will continue to evolve as technology advances, costs fall, and benefits of obtaining this information become more evident. In the absence of known family history of genetic disease, it is reasonable to offer genetic carrier screening to the woman first and test the male partner only if the mother has positive results.

For all women considering pregnancy, current recommendations support offering carrier screening for cystic fibrosis, spinal muscular atrophy, thalassemias, and hemoglobinopathies. Additional testing may be indicated depending on ethnic or racial group, for example, sickle cell screening in African Americans and multiple disorders in the Ashkenazi Jewish population. Importantly, no disorders are found uniquely in a given ethnic or racial group. Moreover, many families may be interracial, and ethnic background may be unknown.

In any patient with POI, karyotype testing for trisomy 21 mosaicism is considered. Likewise, Fragile X premutation carrier screening should be discussed with any woman with a family or personal history of POI or family history of intellectual disability. Additional information regarding genetic testing for POI is found in Chapter 17 (p. 375).

Genetic Screening in the Male

Genetic abnormalities are a relatively common cause of abnormal semen characteristics (American Society for Reproductive Medicine, 2018b). According to current World Health Organization recommendations, karyotype testing should be performed for any male with severe oligospermia ($<5 \times 10^6$ sperm/mL) or nonobstructive azoospermia (Barratt, 2017). Approximately 15 percent of azoospermic men and 5 percent of severely oligospermic men will have an abnormal karyotype. Although genetic abnormalities cannot be corrected, they may have implications for the health of the patient or their offspring. Therefore, karyotyping is pursued when indicated by these poor semen analysis results.

Klinefelter syndrome (47,XXY) will be a frequent finding. This syndrome is observed in approximately 1 in 500 men in the general population and accounts for 1 to 2 percent of male infertility cases. Classically, these men are tall, undervirilized, and have gynecomastia and small, firm testes. As the phenotype varies widely, lack of these characteristics does not preclude chromosomal evaluation. Conversely, a clinician may strongly consider obtaining karyotype testing in any male with these characteristics.

A patient with severely low sperm counts and a normal karyotype is offered testing for microdeletion of the Y chromosome. Up to 15 percent of men with severe oligospermia or azoospermia will have small deletions in a region of the Y chromosome termed the *azoospermia factor region (AZF)*. If the deletion is within the AZFa or AZFb subregions, it is unlikely that viable sperm can be recovered for use in IVF. Most men with an AZFc deletion will have viable sperm at biopsy. However, these deletions should be presumed to be inherited by their offspring. The clinical significance of microdeletions in the recently identified AZFd region is unknown, as these patients have apparently normal spermatogenesis (Hopps, 2003; Pryor, 1997).

Obstructive azoospermia may be due to congenital bilateral absence of the vas deferens (CBAVD). Approximately 70 to 85 percent of men with CBAVD will have mutations found in the cystic fibrosis transmembrane conductance regulator gene (*CFTR* gene), although not all will have clinical cystic fibrosis (Oates, 1994; Ratbi, 2007). Conversely, essentially all men with clinical cystic fibrosis will have CBAVD. Fortunately, testicular function in these men is usually normal, and adequate sperm may be obtained by epididymal aspiration to achieve pregnancy through IVF. Careful genetic counseling and testing of the female partner for carrier status is critical in these situations.

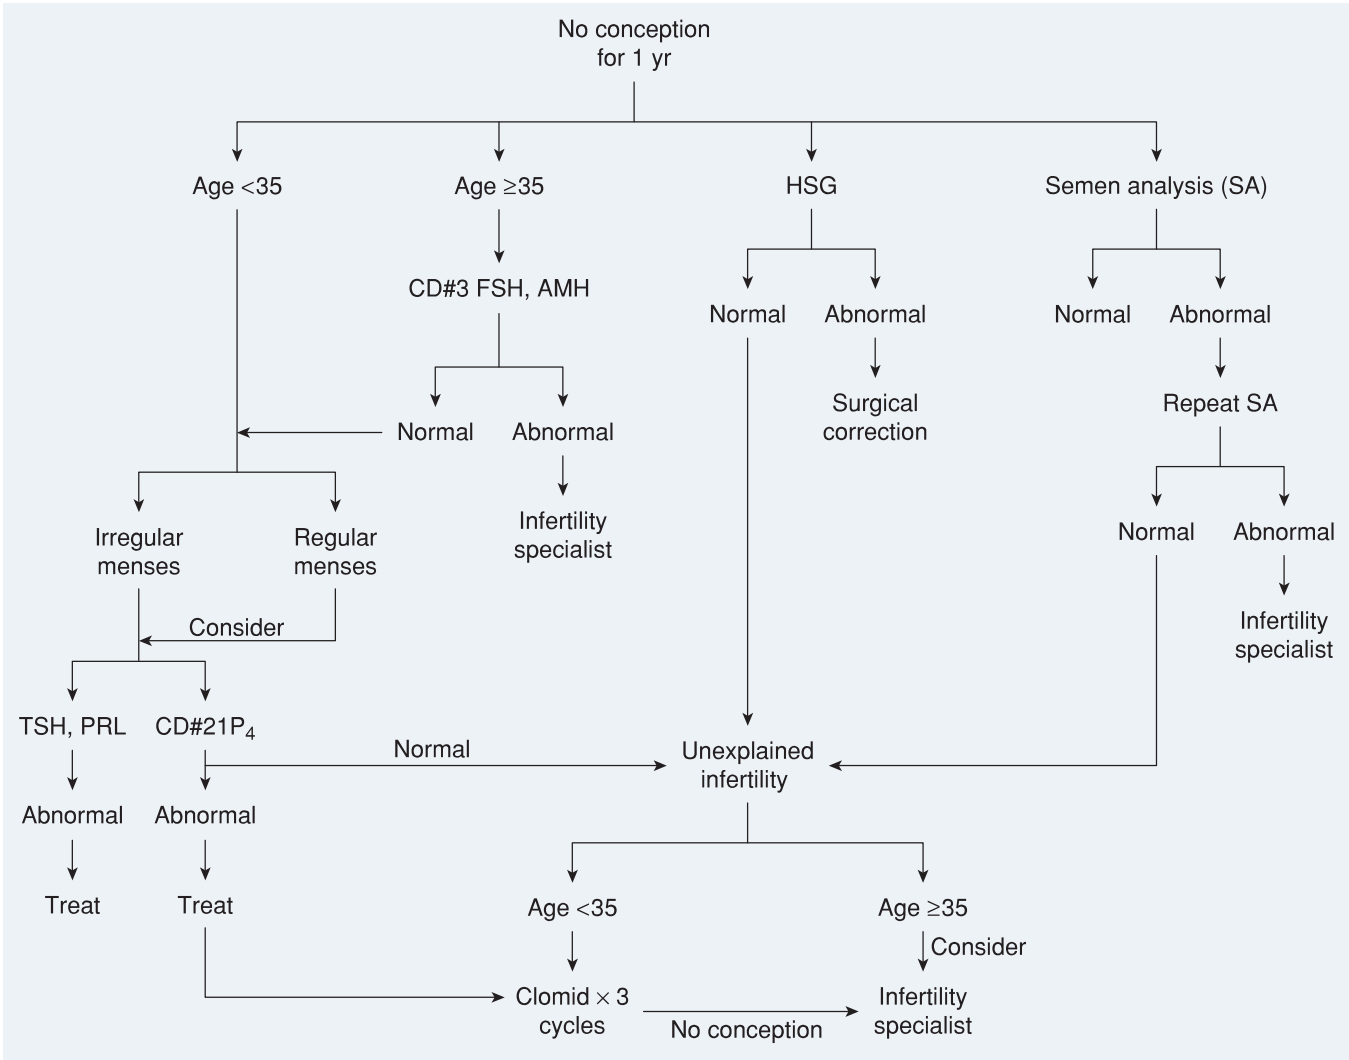

FIGURE 20-10 Diagnostic algorithm for evaluation of the infertile couple. AMH = anti-müllerian hormone; CD#3 = cycle day 3; CD#21 = cycle day 21; FSH = follicle-stimulating hormone; HSG = hysterosalpingography; P_4= progesterone; PRL = prolactin; SA = semen analysis; TSH = thyroid-stimulating hormone.

In excess of 1000 genes are believed to be required for successful sperm development. Mutations in more than 30 of these genes cause of male infertility (Okutman, 2018). Not yet standard practice, as for female infertility patients, well-validated genetic panels are expected to become available for male infertility testing in the future.

CONCLUSION

Figure 20-10 provides an algorithm for the evaluation of an infertile couple. Details will vary between practitioners and will be affected by patient presentation. In general, the female partner has some form of testing to confirm ovulation and to demonstrate normal endometrial cavity anatomy and tubal patency. In older women, evaluation of an early-follicular serum FSH level with or without AMH testing is essential to ensure adequate follicular reserves. The male partner has semen analysis performed. A subset of couples will decline HSG and semen analysis if the woman has a clear ovulatory defect. These couples are reminded that the incidence of couples having two abnormalities is relatively high. These patients may be treated but are strongly encouraged to complete the evaluation if conception does not follow within a few months. Treatment options are discussed in Chapter 21 (p. 451).

Infertility results from diseases of the reproductive system that impair the body's ability to perform basic reproductive function. It is defined as the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse. Earlier evaluation and treatment may be justified based on medical history and physical findings and is warranted after 6 months for women older than 35 (American Society for Reproductive Medicine, 2015a). Ten to 15 percent of the reproductive-aged population is infertile, and men and women are equally affected.

Infertility treatment is a complex process influenced by numerous factors. Important considerations include duration of infertility, a couple's age (especially the female's), and diagnosed cause. Additionally, the level of distress experienced by a couple is factored.

In general, initial steps strive to identify a primary cause and contributing factors. Treatment is aimed at their direct correction and is typically medication or surgery. In many cases, therapy can begin without a complete evaluation, especially if a cause is obvious. However, if pregnancy does not quickly follow, more thorough testing is prudent.

However, evaluation commonly may not yield a satisfactory explanation or may identify causes that are not amenable to direct correction. For such cases, recent advances in assisted reproduction provide effective options. Assisted reproductive technology (ART) employs procedures that at some point require extraction and isolation of an oocyte. These approaches, however, are not without disadvantage. As one example, in vitro fertilization (IVF) is linked to higher rates of some fetal and maternal complications. Appropriate treatments may also pose ethical dilemmas for couples or their physician. For example, selective reduction of a multifetal pregnancy may improve survival chances for some fetuses but at the cost of others. Last, infertility treatment can be a financial burden, a significant source of emotional stress, or both. During consultation, an infertility specialist does not dictate treatment but offers and explains therapy options, which may include expectant management or even adoption.

LIFESTYLE THERAPIES

Weight Optimization

Ovarian function is dependent on weight. Low body-fat content is linked with hypothalamic hypogonadism. In contrast, central body fat is associated with insulin resistance and contributes to ovarian dysfunction in many women with polycystic ovarian syndrome (PCOS). Lifestyle modification in overweight infertile women with PCOS leads to a reduction of central fat and improved insulin sensitivity, decreased hyperandrogenemia, lowered luteinizing hormone (LH) concentrations, and restoration of fertility in many cases (Hoeger, 2001; Kiddy, 1992). Even a 5 to 10 percent reduction in body weight can be successful in women with PCOS (Crosignani, 2003; Kiddy, 1992; Pasquali, 1989). Apart from diet, exercise can also improve insulin sensitivity. Weight loss and exercise are inexpensive and should be recommended as first-line management of obese women with PCOS.

Although pharmacologic options can effectively treat anovulation if weight cannot be lost, obesity alone is a significant risk factor for obstetric and perinatal complications. These include higher rates of gestational diabetes, cesarean delivery, preeclampsia, unexplained stillbirth, and surgical wound infection (Hawkins, 2018). Obesity also is associated with an increased risk of birth defects (American Society for Reproductive Medicine, 2015b). Thus, delaying treatments in morbidly obese women until their body mass index (BMI) can be reduced below 35 should be strongly considered. This is especially true if treatments involve surgical risks or risk of multifetal gestation.

Weight-loss options are discussed in Chapter 1 (p. 14). If bariatric surgery is selected, delaying conception for 1 to 2 years is advised (American Society for Reproductive Medicine, 2015b). Rapid weight loss during this time poses theoretical risks for fetal-growth restriction and nutritional deprivation. However, because these risks remain theoretical, any benefits of postponing pregnancy must be balanced against the risk of

declining fertility with aging. It might be reasonable to consider achieving pregnancy prior to 1 year if weight has stabilized. In any case, women who have undergone bariatric surgery should be evaluated for nutritional deficiencies and the need for vitamin supplementation (American College of Obstetricians and Gynecologists, 2018b).

Undernutrition can also be problematic. The reproductive axis is closely linked to nutritional status, and inhibitory pathways suppress ovulation in subjects with significant weight loss (Chap. 17, p. 378). Anorexia nervosa and bulimia nervosa affect up to 5 percent of reproductive-aged women and may cause amenorrhea, infertility, and, in those who do conceive, an increased likelihood of miscarriage. Fortunately, recovery may follow minimal acquisition of weight because energy balance has a more important effect than body fat.

Exercise

Physical activity has numerous health benefits. The relationship between exercise and fertility, however, is not straightforward. Competitive female athletes often experience amenorrhea, irregular cycles or luteal dysfunction, and infertility. This may be related not specifically to physical activity itself but rather to low body-fat content or physical stress associated with competition. At this time, insufficient data exist to support or discourage physical activity in infertile women in the absence of documented ovarian dysfunction associated with obesity or low body weight.

Nutrition

In the absence of obesity or significant undernutrition, the role of diet in infertility is unclear. High-protein diets and gluten intolerance (celiac disease) have been investigated as underlying causes in women. However, studies sizes have been small, and conflicting results found (Collin, 1996; Jackson, 2008; Meloni, 1999). In men, dietary antioxidants have been proposed as a potential way to improve male reproductive outcomes by reducing oxidative damage in sperm DNA (Ross, 2010). Although the approach is promising, large well-designed studies to guide its clinical use are needed (Patel, 2008). The nutritional supplement carnitine also had been touted as a potential benefit for male infertility. This finding, however, has not been confirmed by a randomized trial (Sigman, 2006).

Despite a lack of conclusive benefits to supplements or diet modification in infertile couples, daily multivitamin supplementation for both is reasonable. Folic acid is contained in most multivitamins, and daily doses of 400 μg orally are recommended for women attempting pregnancy to reduce the incidence of neural-tube defects in their fetuses (American College of Obstetricians and Gynecologist, 2017).

Herbal therapies including traditional Chinese medicine (TCM) and acupuncture have been suggested to enhance fertility either alone or in conjunction with standard therapies including ART. Smith and associates (2010) found that 29 percent of infertile couples seeking pregnancy in the United States had used complementary and alternative medicine. At this time, however, current evidence does not support the benefit of TCM or acupuncture on fertility as a primary or an adjunct treatment (American Society for Reproductive Medicine, 2017).

Stress Management

Stress has been implicated in reproductive failure. Although severe stress can result in anovulation, less significant stress also may play a role by a yet undefined mechanism. Patients with higher stress levels have lower pregnancy rates with IVF treatments (Thiering, 1993). Accordingly, screening all infertile couples for anxiety or depression is a consideration. Although pharmacologic management of stress is not typically recommended during infertility treatments, a "mind/body" approach that combines psychological counseling and meditation may be reasonable for those patients manifesting high levels of anxiety (Domar, 1990).

CORRECTION OF OVARIAN DYSFUNCTION

Hyperprolactinemia

Prolactin is a pituitary hormone with important roles in various reproductive functions, and elevated levels are commonly encountered in clinical endocrinology practice. If hyperprolactinemia is found, then physiologic, pharmacologic, or other secondary causes of hormone hypersecretion are sought (Table 13-2, p. 285).

Dopamine agonists are the primary treatment of hyperprolactinemia (Chap. 16, p. 362). Surgery is only considered for prolactin-secreting adenomas that are resistant to medical therapy or that are large. During pregnancy, if hyperprolactinemia is not associated with a pituitary lesion or a lesion measures <10 mm (microadenoma), then dopamine-agonist therapy is stopped because the tumor-expansion risk is low (Molitch, 1999). If the tumor size is ≥ 10 mm (macroadenoma), bromocriptine (Parlodel) use is advised during pregnancy to avoid significant tumor growth.

Hypothyroidism

Thyroid disorders are prevalent during reproductive years and affect women four to five times more often than men. In women, oligomenorrhea and amenorrhea are frequent findings. Although ovulation and conception can still occur in those with mild hypothyroidism, treatment with thyroxine usually restores a normal menstrual pattern and enhances fertility.

Subclinical hypothyroidism may also be associated with ovarian dysfunction (Strickland, 1990). Lincoln and colleagues (1999) found a 2-percent incidence of elevated thyroid-stimulating hormone (TSH) levels in 704 asymptomatic women seeking evaluation for infertility. Correction of hypothyroidism in those with ovarian dysfunction and elevated TSH levels led to pregnancy in 64 percent. In addition, subclinical hypothyroidism may also adversely affect pregnancy outcomes, but current evidence does not support treatment of subclinical hypothyroidism during pregnancy to improve these outcomes (Casey, 2018). That said, in women seeking treatment for infertility, early detection and treatment of hypothyroidism of any degree is advised.

Ovulation Induction

Ovarian dysfunction is the most common indication for the use of medications to induce ovulation. These agents can also be selected for ovulatory women to enhance the likelihood of

pregnancy in couples with other causes of infertility or unexplained infertility. Use of these to promote multifollicular development and prompt ovulation is called *superovulation* or *ovulation enhancement*. If these agents are administered solely to stimulate follicles and then egg harvesting is completed by ART, the termed *controlled ovarian stimulation (COS)* is used. We prefer the term *ovulation induction* to describe treatment with medications to stimulate normal (ideally monofollicular) ovulation in women with ovarian dysfunction.

Frequent causes of ovarian dysfunction include PCOS and diminished ovarian reserve. Less often, central (hypothalamic or pituitary) disorders or thyroid dysfunction can result in infertility (Table 17-3, p. 373). Rarely, ovarian tumors or adrenal abnormalities lead to abnormal ovarian function. Treatment of ovarian dysfunction is based on the identified cause and the results of any prior attempted therapy.

Clomiphene Citrate

Clomiphene citrate (CC) is the initial treatment for most anovulatory infertile women. Chemically similar to tamoxifen, CC is a nonsteroidal triphenylethylene derivative that demonstrates both estrogen agonist and antagonist properties. Antagonist properties predominate except at very low estrogen levels. As a result, negative feedback that is normally produced by estrogen in the hypothalamus is reduced (Fig. 21-1). Gonadotropin-releasing hormone (GnRH) secretion is altered and stimulates pituitary gonadotropin release. The resulting increase in follicle-stimulating hormone (FSH) levels, in turn, drives ovarian follicular activity.

Tamoxifen also has been used successfully for ovulation induction. However, it is not Food and Drug Administration (FDA) approved for this indication and does not offer significant advantage compared with CC.

CC is administered orally, typically starting on the third to fifth day after the onset of spontaneous or progestin-induced menses. Ovulation rates, conception rates, and pregnancy outcomes are similar whether treatment begins on cycle day 2, 3, 4, or 5. Prior to therapy and to avoid complications, sonography is advised to exclude significant spontaneous follicular maturation or residual follicular cysts. In general at our institution, clomiphene can be administered if no follicle is >20 mm and the endometrium is less than 5 mm. Both reflect minimal ovarian activity. Significant activity would complicate cycle stimulation. A pregnancy test is also indicated after spontaneous menses. Although not a proven teratogen, CC is classified as category X by the FDA and thus is contraindicated in suspected or documented pregnancy.

The dose required to achieve ovulation correlates with body weight. However, no reliable method accurately predicts the effective dose in an individual woman (Lobo, 1982). Consequently, CC is titrated empirically to establish the lowest productive dose for each patient. Treatment typically begins with a single 50-mg tablet taken daily for 5 consecutive days. Doses are increased by a 50-mg increment in each subsequent cycle until ovulation is induced. The dose of CC should not be increased if normal ovulation is confirmed. Thus, lack of pregnancy alone does not justify a dose increase. The effective dose of CC ranges from 50 mg/d to 250 mg/d, although doses in excess of 100 mg/d

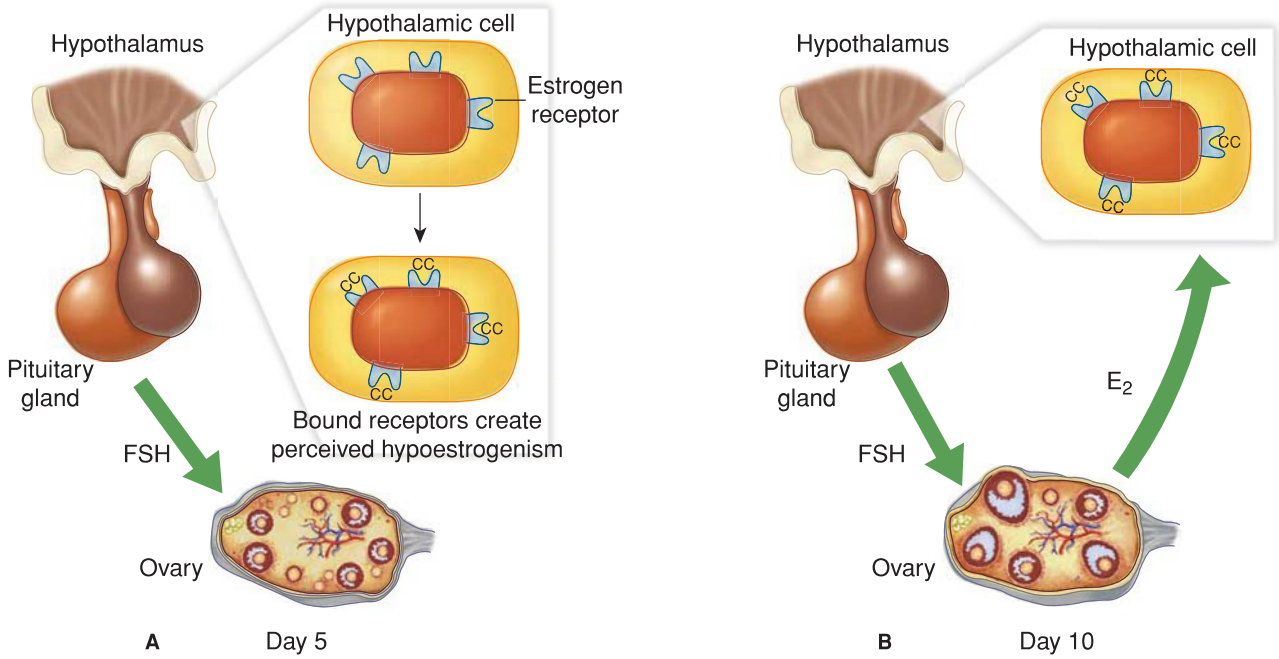

FIGURE 21-1 Effect of clomiphene citrate (CC) administration. **A.** Early in the cycle, CC binds to the estrogen receptor in the pituitary and hypothalamus. This causes an effective reduction in hypothalamic estrogen receptor number. Because of this reduced receptor number, the hypothalamus and pituitary are blinded to true circulating estrogen levels and perceived hypoestrogenism results. As a result, estrogen's negative feedback is interrupted centrally, and follicle-stimulating hormone (FSH) secretion increases from the anterior pituitary. This leads to maturation of multiple follicles. **B.** By the late follicular phase, because of CC's long retention within tissues, estrogen receptor depletion continues centrally. As a result, enhanced estradiol (E_2) secretion from the ovary is not capable of exerting normal negative feedback on FSH release. This leads to a growth of multiple dominant follicles and multiple ovulations.

TABLE 21-1. Gonadotropin Preparations Used for Ovulation Induction

Name	Product Type	Derivation	FSH Activity	LH or hCG Activity
Gonal-f or Bemfola	Follitropin alpha	Recombinant FSH	Yes	None
Follistim or Puregon	Follitropin beta	Recombinant FSH	Yes	None
Rekovelle	Follitropin delta	Recombinant FSH	Yes	None
Elonva	Follitropin gamma	Recombinant FSH	Yes	None
Menopur	Menotropin	Highly purified, urine-derived	Yes	hCG

FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin.

are not approved by the FDA and have low likelihood of success. Some studies suggest that adjunctive glucocorticoid therapy may benefit some patients not responsive to CC alone (Elnashar, 2006; Parsanezhad, 2002). The precise mechanism is unclear. This therapy may be empiric or individualized based on elevated dehydroepiandrosterone sulfate (DHEAS) levels.

In general, women failing to ovulate with a dose of 100 mg/d or failing to conceive following 3 to 6 months of ovulatory response to CC should be considered candidates for alternative treatments. In one study, 84.5 percent of pregnancies achieved with ovulation induction occurred during the first three ovulatory cycles (Gysler, 1982).

Insulin-Sensitizing Agents

Many women with PCOS exhibit insulin resistance (Chap. 18, p. 399). Insulin resistance leads to compensatory hyperinsulinemia and dyslipidemia. Given that hyperinsulinemia plays a pathogenic role in PCOS development, reduction of circulating insulin levels in women with PCOS may restore normal reproductive endocrine function. As discussed, weight loss, nutrition, and exercise clearly can lead to reduced hyperinsulinemia, resolution of hyperandrogenism, and in some cases, resumption of ovulatory function in overweight women with PCOS. However, women may be poorly compliant, and weight loss is rarely maintained over time.

Insulin-sensitizing agents have been proposed for the treatment of PCOS. In patients with insulin resistance, these compounds enhance target tissue responsiveness to insulin and thereby reduce the need for compensatory hyperinsulinemia (Antonucci, 1998). Current insulin-sensitizing agents include the biguanides and thiazolidinediones (Chap. 18, p. 401).

Of these, studies suggest that metformin (Glucophage) increases the frequency of spontaneous ovulation, menstrual cyclicity, and the ovulatory response to CC in women with PCOS (Nestler, 1998; Palomba, 2005; Vandermolen, 2001). Doses are 500 mg orally three times daily or 850 mg twice daily with meals. In contrast, a large, randomized trial failed to support the hypothesis that metformin, either alone or in combination with CC, improves the live-birth rate in women with PCOS (Legro, 2007). This study emphasizes the use of live birth as the primary endpoint for efficacy rather than intermediate or surrogate endpoints.

Gonadotropins

CC is easy to use and leads to ovulation in most patients (Hammond, 1983). However, reported cumulative pregnancy rates are disappointing and range from approximately 25 to 50 percent (Legro, 2007; Raj, 1977; Zarate, 1971). Lower than expected pregnancy rates with CC are attributed to its long half-life and peripheral antiestrogenic effects, mainly on the endometrium and cervical mucus. For such individuals, who are often classified as "clomiphene resistant," the next step is traditionally the administration of exogenous gonadotropin preparations via injections.

As with CC, the goal of ovulation induction with gonadotropins is simply to reestablish normal ovarian function. Ideally, the dose used is the minimum required to cause normal development of a single dominant follicle. Because the response to gonadotropins can differ greatly among women and even among cycles, intensive monitoring is required to adjust dosage and ovulation timing.

Gonadotropin preparations vary in terms of their source (urinary or recombinant) and by the presence or absence of LH activity (Table 21-1). Human menopausal gonadotropin (hMG) preparations were the first gonadotropin option, and agents in this class are termed *menotropins*. hMG products contain both FSH and LH activity. These medications are extracted and purified from the urine of postmenopausal women, which is a cohort with normally high FSH, LH, and human chorionic gonadotropin (hCG) levels. In the past, hMG preparations contained both LH and hCG as dual sources of LH activity (Filicori, 2002). Remember, LH and hCG both bind to the same receptor (luteinizing hormone/chorionic gonadotropin receptor [LHCGR]).

In the older, non-highly purified hMG products, significant non-gonadotropin contaminants were present. This is not true for the current generation of highly purified menopausal gonadotropin (HP-hMG) products. In currently available HP-hMG products, hCG serves as the primary/sole source of LH activity. Highly purified urinary preparations allow for administration by a subcutaneous route with minimal or no reaction at the injection site. Alternatives to hMG include purified recombinant FSH, discussed next.

Both LH and FSH activity are required for normal ovarian steroidogenesis and follicular development. In many cases, pure FSH preparations can be used because of adequate endogenous LH production. For example, ovulation induction in women with PCOS can be performed with products containing only FSH or with those containing both LH and FSH activity. At present, data do not support the superiority of one preparation compared with another. However, for ovulation induction in

patients with hypogonadotropic amenorrhea, LH activity also must be provided from an exogenous source. For this, options include just-described hMG, recombinant LH, and low-dose (diluted) urinary or recombinant hCG. Pulsatile GnRH can be used to induce ovulation in these patients, although this is not yet widely available.

When used for ART, gonadotropin preparations are nearly always paired with GnRH analogues (agonist or antagonist). These analogues help avoid premature LH surge and early ovulation. However, because of the absent LH activity induced by GnRH agents, high serum FSH levels can result in elevated follicular-phase progesterone concentrations due to greater production from granulosa cells and to impaired steroid metabolism from theca cells (Fleming, 2010). As one remembers from the two-cell theory of estrogen production, progesterone is first metabolized to androgens by theca cells, and granulosa cells then convert androgens to estrogen. Thus, with impaired theca metabolism, progesterone can accumulate (Chap 16, p. 356). Progesterone levels >1.5 ng/mL in the follicular phase alter endometrial gene expression and lower pregnancy rates, most likely through poor implantation (Bosch, 2010; Laberta, 2011). Gonadotropin products containing LH/hCG activity induce *CYP17* gene expression in the theca cells and thereby promote the conversion of progesterone into androgens. These androgens are then converted into estrogen by the follicle's granulosa cells. Accordingly, HP-hMG cause fewer premature elevations in progesterone compared with recombinant FSH. In the United States, combined use of HP-hMG and recombinant FSH ("mixed protocols") for ovarian stimulation for ART is common.

Currently four different recombinant FSH products are commercially available. The first two (follitropin alpha and follitropin beta) are produced in Chinese hamster ovary (CHO) cell lines. Because they have different glycosylation structure/isoforms, they are considered different molecules. A long-acting FSH (follitropin gamma) is commercially available outside the United States. This recombinant molecule was created by adding a DNA sequence to the human gene that encodes the FSH beta subunit. This extra sequence allows for more glycosylation and hence a prolonged clearance. More recently, a novel recombinant FSH (follitropin delta) has been produced from a human embryonic retinal cell line (PER.C6) (Koechling, 2017). Low-molecular-weight molecules (nonproteins) can activate FSH and LH receptors. However, these compounds have not progressed beyond early stages of clinical development. Potential advantages of these nontraditional gonadotropins could include oral delivery.

Most clinicians begin ovulation induction attempts at a low gonadotropin dosage of 50 to 75 IU/d. This is gradually increased if no ovarian response (as assessed by serum estradiol measurements) is noted after several days (Fig. 21-2). This is referred to as a "step-up" protocol. A "step-down" protocol can also be used and offers a shorter duration of stimulation. However, the risk of excessive ovarian response, such as multiple follicle development or ovarian hyperstimulation syndrome, may be higher with this method. With either approach, if a patient fails to conceive, subsequent cycles may be started at higher doses based on prior response.

In general, gonadotropin stimulation in women with PCOS is less successful than in patients with hypogonadotropic amenorrhea (Balen, 1994). Women with PCOS have ovaries highly sensitive to gonadotropin stimulation. They have a higher risk of excessive ovarian response and of multifetal pregnancy than do those with normal ovaries (Farhi, 1995).

Aromatase Inhibitors

Gonadotropins are associated with more effective ovulation induction and higher pregnancy rates than CC. However, gonadotropins are expensive and carry higher risks for ovarian hyperstimulation syndrome and multifetal gestation. Accordingly, aromatase inhibitors have been investigated as ovulation-inducing agents (Fig. 21-3). These drugs were originally developed for breast cancer treatment and effectively inhibit *aromatase*, a cytochrome P450 hemoprotein that catalyzes the rate-limiting step in estrogen production. Aromatase inhibitors are orally administered, easy to use, relatively inexpensive, and associated with typically minor side effects (Chap. 13, p. 295).

The most widely used aromatase inhibitor to induce ovulation in anovulatory and ovulatory infertile women is letrozole (Femara). Its typical dosage is 2.5 to 5 mg orally daily for 5 days. Compared with CC, its use yields higher pregnancy rates following ovulation induction (Legro, 2014). When combined with gonadotropins (for ovulation induction), letrozole leads to lower gonadotropin requirements and may achieve pregnancy rates comparable to gonadotropin treatment alone (Casper, 2003; Mitwally, 2004). This contrasts with letrozole's lower success rate when coupled with intrauterine insemination (IUI) in patients with unexplained infertility (Diamond, 2015).

Data suggesting that letrozole use for infertility treatment might be associated with a higher risk of congenital cardiac and bone malformations in the newborn are contradictory (Biljan, 2005; Tulandi, 2006). However, in 2005, the manufacturer issued a statement to physicians worldwide advising that letrozole use in premenopausal women, specifically its use for ovulation induction, is contraindicated (Fontana, 2005). As a result, it is not likely that letrozole will gain FDA approval or widespread acceptance for ovulation induction in the near future. Larger, well-designed randomized trials are still needed (Franik, 2014).

A second aromatase inhibitor, anastrozole (Arimidex), is of the same compound class as letrozole and also is approved for breast cancer treatment. At this time, no concerns have been raised regarding its teratogenicity. However, experience with anastrozole in ovulation induction at this time is limited, and ideal dosages are currently unknown. Two trials comparing anastrozole to CC have not found it to be more effective (Tredway, 2011a,b).

Complications of Fertility Drugs

Ovarian Hyperstimulation Syndrome. This is a clinical symptom complex associated with ovarian enlargement resulting from exogenous gonadotropin therapy. Symptoms may include abdominal pain and distention, ascites, gastrointestinal problems, respiratory compromise, oliguria, hemoconcentration, and thromboembolism. These symptoms may develop during ovulation induction or in early pregnancies that were conceived through exogenous ovarian stimulation.

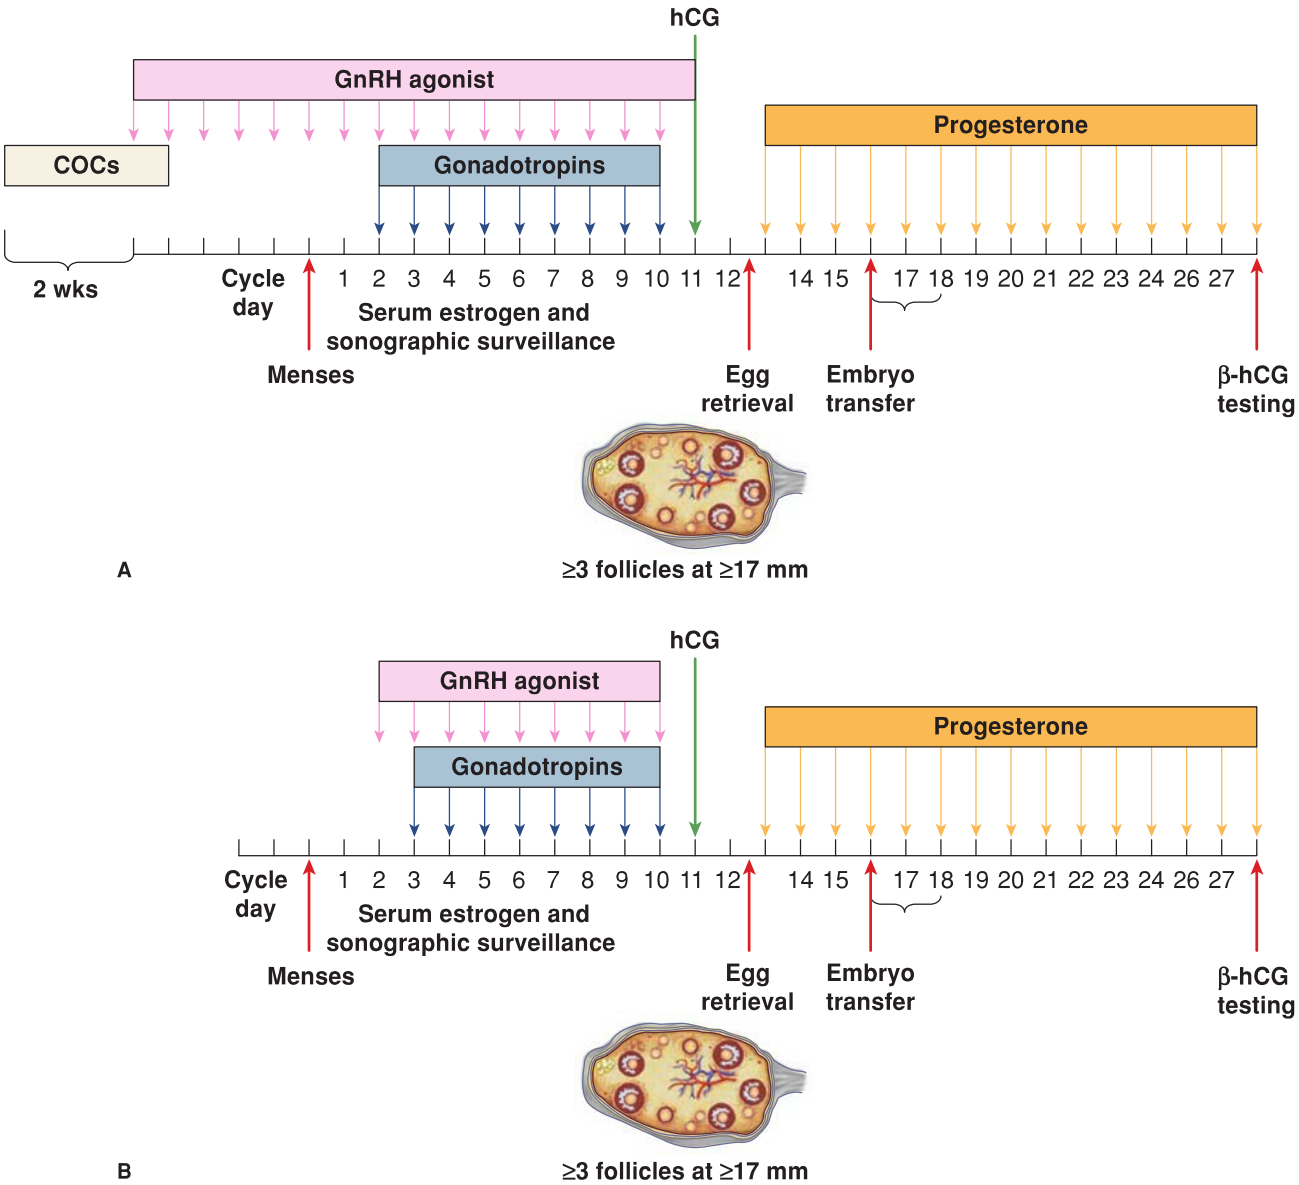

FIGURE 21-2 Drug protocols for ovulation induction. **A.** Downregulation of gonadotropin-releasing hormone (GnRH) agonist protocol. This is also known as the *long protocol*. In this diagram, the long protocol is combined with combination oral contraceptive (COC) pill pretreatment. With the long protocol, GnRH agonists are begun typically 7 days prior to gonadotropins. GnRH agonists suppress endogenous pituitary release of gonadotropins. This minimizes the risk of a premature luteinizing hormone (LH) surge and thus premature ovulation. During all protocols, serial serum estrogen levels and sonographic surveillance of follicular development accompany gonadotropin administration. Human chorionic gonadotropin (hCG) is administered to mimic the normal luteinizing hormone (LH) surge and trigger ovulation. HCG is given when sonography shows three or more follicles measuring at least 17 mm. Eggs are retrieved 36 hours later. Embryos are transfer back to the uterus 3–5 days following retrieval. Progesterone supplementation, with either vaginal preparations or intramuscular injection, follows during the luteal phase to support the endometrium. One major drawback of GnRH agonist therapy is the induction of initial transient gonadotropin release or *flare*, which may lead to ovarian cyst formation. Functional ovarian cysts can prolong the duration of pituitary suppression required prior to gonadotropin initiation and may also exert a detrimental effect on follicular development because of their steroid production. However, COC pretreatment can help prevent ovarian cyst formation. Moreover, COC pretreatment may improve induction results by providing an entire cohort of follicles synchronized at the same developmental stage that will reach maturity at the same time once stimulated by gonadotropins. **B.** GnRH flare protocol. This is also known as the *short protocol*. GnRH agonists initially bind gonadotropes and stimulate follicle-stimulating hormone (FSH) and LH release. This initial flare of gonadotropes stimulates follicular development. Following this initial surge of gonadotropins, the GnRH agonist causes receptor downregulation and an ultimately hypogonadotropic state. Gonadotropin injections begin 2 days later to continue follicular growth. As with the long protocol, continued GnRH agonist therapy prevents premature ovulation. (*Continued*)

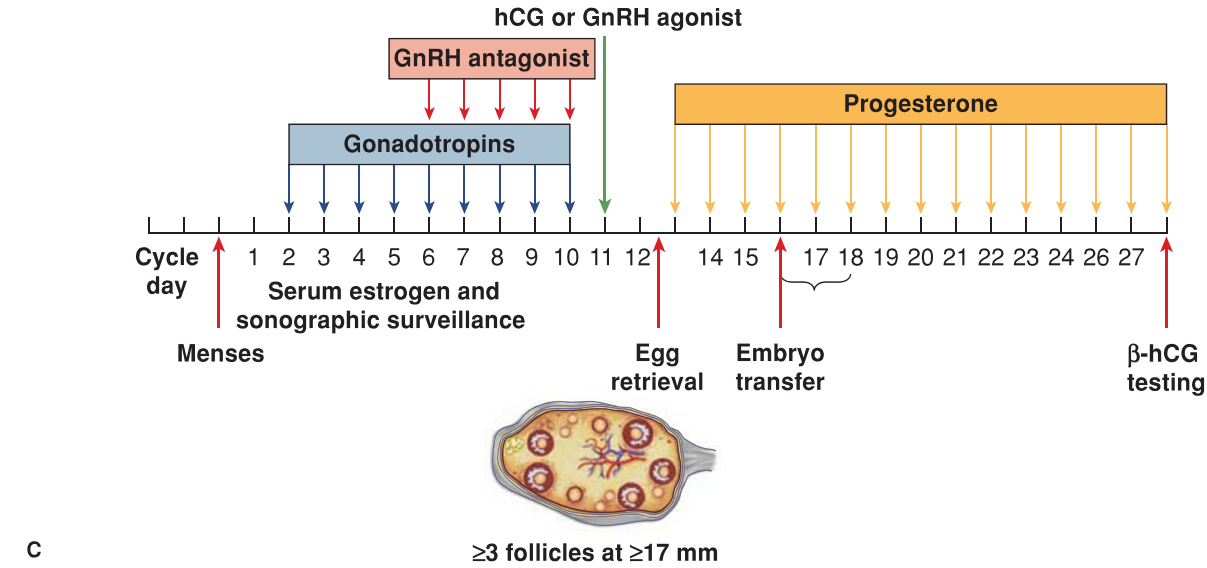

FIGURE 21-2 (*Continued*) **C.** GnRH antagonist protocol. As with GnRH agonists, these agents are combined with gonadotropins to prevent premature LH surge and ovulation. This protocol attempts to minimize risk of ovarian hyperstimulation syndrome (OHSS) and GnRH side effects, such as hot flashes, headaches, bleeding, and mood changes.

The etiology of ovarian hyperstimulation syndrome (OHSS) is complex, but hCG, either exogenous or endogenous (derived from a resulting pregnancy), is believed to be an early contributing factor. Development of OHSS involves greater vascular permeability and subsequent loss of fluid, protein, and electrolytes into the peritoneal cavity, which leads to hemoconcentration. Enhanced capillary permeability is felt to result from vasoactive substances produced by the corpus luteum. Vascular endothelial growth factor (VEGF) is thought to play a major role, and angiotensin II may also be involved. Hypercoagulability may be related to hyperviscosity following hemoconcentration. Alternatively, it may stem from simultaneous high estrogen levels, and these high levels can raise coagulation factor production. Predisposing factors for OHSS include multifollicular ovaries such as with PCOS, young age, high estradiol levels during ovulation induction, and pregnancy.

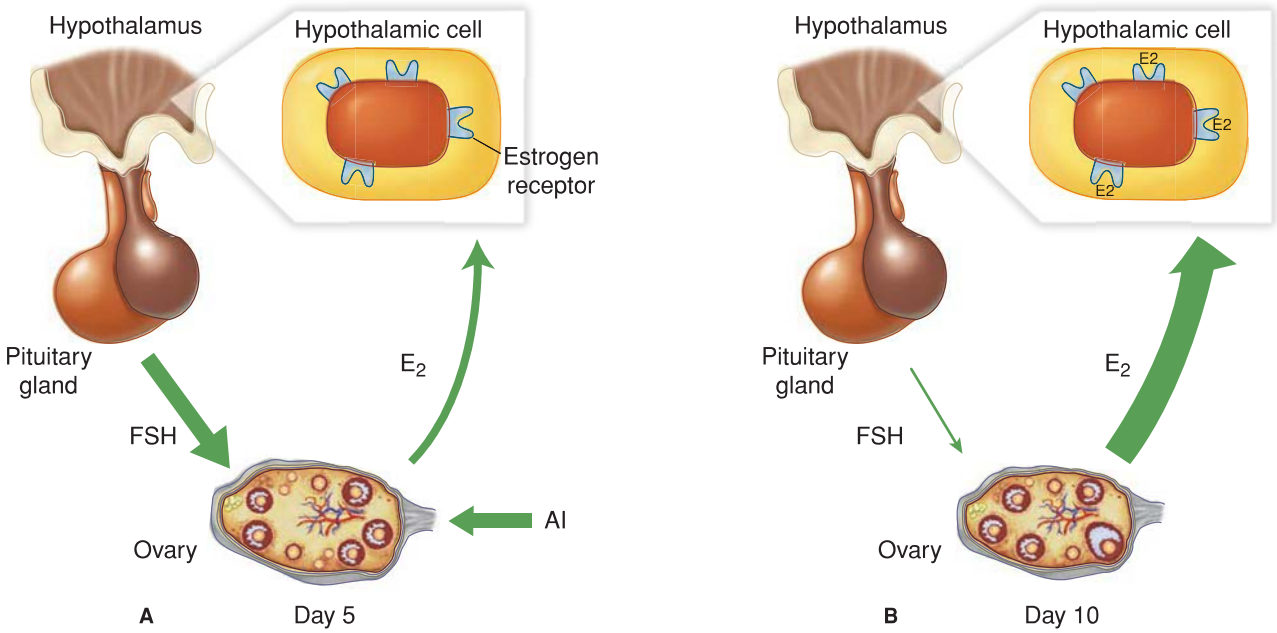

FIGURE 21-3 Effect of aromatase inhibitor (AI) administration. **A.** Administration suppresses ovarian estradiol (E_2) secretion and reduces estrogen-negative feedback at the pituitary and hypothalamus. As a result, increased follicle-stimulating hormone (FSH) secretion from the anterior pituitary stimulates growth of multiple ovarian follicles. **B.** Later in the follicular phase, the effect of the aromatase inhibitor is reduced, and E_2 levels rise as a result of follicular growth. Because AIs do not affect estrogen receptors centrally, the higher E_2 levels result in normal central negative feedback on FSH secretion. Follicles smaller than the dominant follicle undergo atresia, with resultant monofollicular ovulation in most cases.

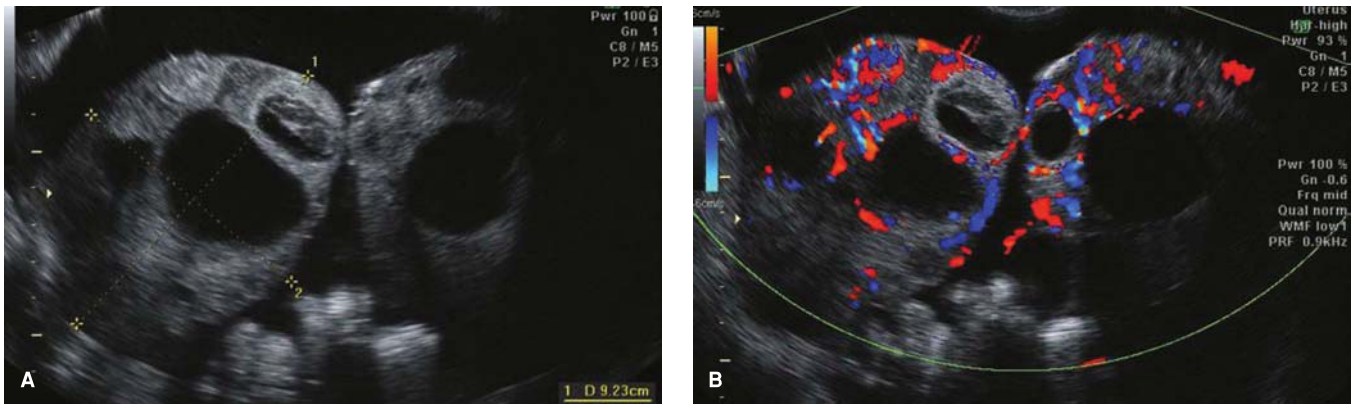

FIGURE 21-4 A. Transvaginal sonogram of ovaries with multiple, large cysts secondary to ovarian hyperstimulation syndrome (OHSS). Ovaries are enlarged and meet in the midline. Ascites surrounds these enlarged ovaries. **B.** Color Doppler transvaginal sonography is often performed to help exclude ovarian torsion in these patients.

Abdominal pain is prominent and caused by ovarian enlargement and accumulation of peritoneal fluid. Although sonographic examination of women with OHSS usually reveals enlarged ovaries with numerous follicular cysts and ascites, OHSS is a clinical diagnosis (Fig. 21-4). Several different classification schemes have been proposed to categorize the severity of this syndrome, and Table 21-2 lists one (Golan, 1989).

OHSS treatment is generally supportive. Paracentesis is typically performed transvaginally as an outpatient and can ameliorate abdominal discomfort and relieve respiratory distress. Reaccumulation of ascites may prompt additional paracenteses or rarely placement of a percutaneous "pigtail" catheter for continuous drainage. Untreated hypovolemia can lead to renal, hepatic, or pulmonary end-organ failure. Thus, fluid balance must be maintained by replacement with an isotonic fluid such as normal saline. Monitoring of electrolytes is critical. Because of hypercoagulability in these women, prophylaxis for thromboembolism is strongly considered with severe OHSS.

During exogenous ovulation, strategies to avoid OHSS induction include decreasing follicular stimulation (a lowered FSH dose), "coasting" (withholding FSH administration for one or more days prior to the hCG trigger injection), prophylactic treatment with volume expanders, and substitution of hCG for FSH during the final days of ovarian stimulation. With this last strategy, low-dose hCG administration can support maturation of larger ovarian follicles but is postulated to directly or indirectly raise atresia rates of small antral follicles and thereby lower OHSS rates. However, during ovulation induction, if concern for OHSS develops, the hCG trigger can be withheld, resulting in cycle cancellation. For these patients, IVF with its egg retrieval before ovulation should often be considered rather than further attempts at inducing ovulation.

OHSS can also develop with ART therapy, and the risk can be substantially reduced with appropriate precautions. Women who are predicted to be especially sensitive to gonadotropins are those with a high number of antral follicles sonographically, a high serum antimüllerian hormone (AMH) level, or a prior robust response to ovulation induction. These individuals should be stimulated with a GnRH antagonist protocol. This allows a single GnRH agonist dose to be used for the "trigger" in place of hCG. The resulting endogenous LH surge can bring about the final stages of follicle and oocyte maturation without significant OHSS risk. As a second preempting option, prevention of pregnancy does not completely eliminate the risk of OHSS but certainly serves to limit symptom duration. Thus, in ART cycles, all embryos can be frozen and embryo transfer postponed. Last, good evidence suggests that dopamine agonists such as cabergoline started at the trigger of ovulation can reduce OHSS incidence (American Society for Reproductive Medicine, 2016).

TABLE 21-2. Classification and Staging of Ovarian Hyperstimulation Syndrome

Grade 1:	Abdominal distention/discomfort
Grade 2:	Grade 1 plus nausea and vomiting or diarrhea Ovaries enlarged and measure 5–12 cm
Grade 3:	Sonographic evidence of ascites
Grade 4:	Clinical evidence of ascites or hydrothorax or difficulty breathing
Grade 5:	All of the above plus decreased blood volume, hemoconcentration, diminished renal perfusion and function, and coagulation abnormalities

Multifetal Gestation. From 1980 through 1997, the number of twin births rose by more than 50 percent, and the number of higher-order multifetal births increased by more than 400 percent (Fig. 21-5) (Martin, 1999). Using data from these years, the Centers for Disease Control and Prevention (CDC) (2000) estimated that approximately 20 percent of triplets and higher-order multifetal births were attributable to spontaneous events; 40 percent were related to ovulation-inducing drugs without ART; and 40 percent resulted from ART. However, further analysis of the same data indicates that most multifetal births result from spontaneously conceived twin gestations and that only approximately 10 percent result from IVF and related procedures.

Higher-order multifetal pregnancy is an adverse outcome of infertility treatment. In general, higher fetal number raises the risk of perinatal and maternal morbidity and mortality.

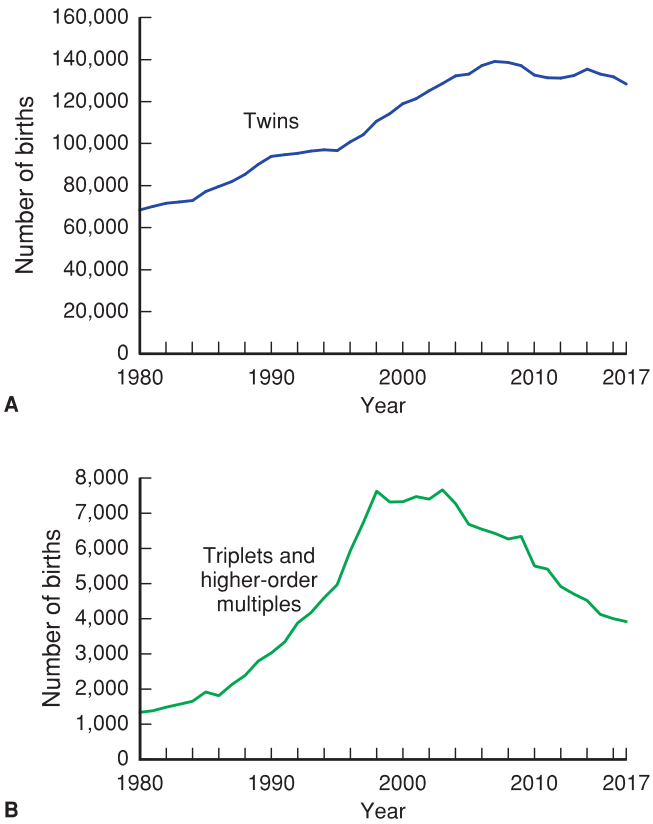

FIGURE 21-5 Trends in frequency of multifetal gestations from 1980 to 2017. **A.** Number of twin births in the United States. **B.** Number of triplet and higher-order multifetal births. (Data from Martin, 2013, 2018.)

Prematurity leads to most adverse events in these cases, but fetal-growth restriction and discordance are other potential factors.

Rates of monozygotic gestation also rise in ovulation induction and ART and are associated with greater fetal risks. These include a three- to fivefold higher perinatal mortality rate compared with that of dizygotic twins. Abnormal placentation also develops frequently. Additionally, compared with singleton neonates, monozygotic twins have congenital anomaly rates that are two- to threefold higher and that approximate 10 percent. Initially, extended embryo culture and zona manipulation were postulated to increase the risk of monozygosity. More recent, well-designed trials have refuted this contention (Franasiak, 2015; Papanikolaou, 2010).

Patients with higher-order multifetal gestations are faced with options of continuing their pregnancy with all the risks previously described, terminating the entire pregnancy, or selecting multifetal pregnancy reduction (MFPR). MFPR reduces the number of fetuses to decrease the risk of maternal and perinatal morbidity and mortality. Although MFPR lowers the risks associated with preterm delivery, it often creates profound ethical dilemmas. Moreover, multifetal reduction lowers, but does not eliminate, the risk of fetal-growth restriction in remaining fetuses. With MFPR, pregnancy loss and prematurity are primary risks. However, current data suggest that such complications have decreased as experience with the procedure has grown (Evans, 2008).

Several issues in infertility care contribute to the increased incidence of higher-order multifetal pregnancies. An infertile couple's sense of urgency may lead to a preference for more aggressive strategies involving gonadotropin treatment or for more embryos to be transferred in IVF cycles. Clinicians may feel competitive pressures to achieve higher pregnancy rates and may be inclined to turn to superovulation or IVF earlier in treatment or to transfer a greater number of embryos.

Efforts to lower the multifetal gestation rates in patients undergoing ovulation induction or superovulation include serum estradiol limits and arbitrary sonographic criteria of follicular size. These, however, have been ineffective. In one randomized clinical trial involving 1255 ovulation induction cycles, hCG was withheld if the estradiol concentration rose above 3000 pg/mL or if more than six follicles greater than 18 mm in diameter were present (Guzick, 1999). Despite these limits on hCG administration, the multifetal gestation rate was still 30 percent. Although sonography and serum estradiol monitoring have not reduced the incidence of multifetal gestation or OHSS, the risk of multifetal pregnancy does correlate with the magnitude of follicular response as indicated by follicle number and serum estradiol levels. However, no consensus among centers has been reached regarding specific sonographic criteria or estradiol levels beyond which hCG should not be administered.

When the likelihood of multifetal gestation is felt to be excessive, IVF can be undertaken to reduce the risk. Because the number of embryos transferred can be strictly controlled, this strategy can minimize the risk of higher-order multifetal gestations. Guidelines set forth by the American Society for Reproductive Medicine and the Society for Assisted Reproductive Technology (2017) have significantly reduced the rates of triplet and higher-order gestations (Table 21-3).

TABLE 21-3. Recommended Limits on the Numbers of Embryos to Transfer

	Age			
Prognosis	**<35 yr**	**35–37 yr**	**38–40 yr**	**41–42 yr**
Cleavage-stage embryos[a]				
Euploid	1	1	1	1
Other favorable[b]	1	1	≤3	≤4
All others	≤2	≤3	≤4	≤5
Blastocysts[a]				
Euploid	1	1	1	1
Favorable[b]	1	1	≤2	≤3
All others	≤2	≤2	≤3	≤3

[a]Justification for transferring additional embryos beyond the recommended limits should be clearly documented in the patient's medical record.
[b]Other favorable = any one of these criteria. *Fresh cycle*: expectation of 1 or more high-quality embryos available for cryopreservation, or previous live birth after an IVF cycle. *FET cycle*: availability of vitrified day-5 or day-6 blastocysts, euploid embryos, 1st FET cycle, or previous live birth after an IVF cycle. FET = frozen embryo transfer; IVF = in vitro fertilization. American Society for Reproductive Medicine, 2017, with permission.

Efforts to reduce twin pregnancies through a greater use of elective single embryo transfer (eSET) are currently ongoing (Paulson 2017).

Ovarian Drilling

Surgical ovarian wedge resection was the first established treatment for anovulatory PCOS patients. It was largely abandoned because of postsurgical adhesion formation, which converted endocrinologic subfertility to mechanical subfertility (Adashi, 1981; Buttram, 1975; Stein, 1939). As a result, it was replaced by medical ovulation induction with CC and gonadotropins (Franks, 1985). However, medical ovulation induction, as discussed, has limitations. Thus, surgical therapy using laparoscopic techniques and termed *laparoscopic ovarian drilling* is an alternative in certain women resistant to medical therapies.

During laparoscopic ovarian drilling, electrosurgical coagulation, laser vaporization, or Harmonic scalpel may be used to create multiple perforations into the ovarian surface and stroma (Section 44-7, p. 1036). In many uncontrolled observational studies, drilling led to temporary, higher rates of spontaneous postoperative ovulation and conception or to improved medical ovulation induction (Armar, 1990, 1993; Farhi, 1995; Greenblatt, 1987; Kovacs, 1991).

The mechanism of action with laparoscopic ovarian drilling is thought to be similar to that of ovarian wedge resection. Both procedures destroy ovarian androgen-producing tissue and reduce peripheral conversion of androgens to estrogens. Specifically, a fall in serum levels of androgens and LH and a rise in FSH levels follow ovarian drilling (Armar, 1990; Greenblatt, 1987). Endocrine changes after surgery are thought to convert the adverse androgen-dominant intrafollicular environment to an estrogenic one and to restore the hormonal environment to normal by correcting ovarian-pituitary feedback disturbances (Aakvaag, 1985; Balen, 1993). Thus, both local and systemic effects are believed to promote follicular recruitment and maturation and subsequent ovulation.

Risks of ovarian drilling include postoperative adhesion formation and the other risks of laparoscopic surgery (Chap. 41, p. 875). Additionally, theoretical risks of diminished ovarian reserve and premature ovarian failure remain to be well investigated. As surgery is more invasive, ovarian drilling is generally not offered prior to consideration of medical therapies.

CORRECTION OF DIMINISHED OVARIAN RESERVE

Ovarian dysfunction may result from ovarian failure or from a diminished ovarian reserve, either of which may follow normal aging, disease, cancer treatment, or ovarian surgery. Even if a woman is spontaneously menstruating, a basal (day 2 or 3) FSH level above 15 IU/L predicts that medical therapies including exogenous gonadotropins will be of little benefit. For these women, the option of using donor eggs should be considered (p. 466). Expectant management also may be considered, although the likelihood of pregnancy is low. Serum AMH levels can identify patients with diminished ovarian reserve prior to the elevation of basal FSH. AMH varies little throughout the menstrual cycle and can be drawn at any time. Although patients with a low AMH level (<1 ng/mL) generally respond poorly to gonadotropins, some may benefit from ART.

CORRECTION OF ANATOMIC ABNORMALITIES

Anatomic distortions of the female reproductive tract are a major cause of infertility and may prevent ovum entry into the fallopian tube; impair transport of ova, sperm, or embryos; or interfere with implantation. The three primary types of anatomic abnormalities include tubal factors, peritoneal factors, and uterine factors. Each has differing effects and therefore may require different therapies.

Tubal Factors

Tubal occlusion can arise from congenital abnormality, infection, or iatrogenic causes. Additionally, a small subset of tubal infertility is idiopathic. Not only the cause of tubal damage but also the nature of an anatomic abnormality is important. For example, proximal tubal occlusion, distal tubal occlusion, and tubal absence differ markedly in their treatment.

Proximal tubal occlusion describes obstruction proximal to the fimbria and may develop at the tubal ostium, isthmus, or ampulla. *Midtubal occlusion* is considered a subset of proximal occlusion. Proximal tubal occlusion may be secondary to tubal resection, luminal obliteration, or simple plugging with mucus or debris. In contrast, *distal tubal occlusion* describes obstruction at the tube's fimbria. It typically results from prior pelvic infection and may be associated with concomitant adnexal adhesions.

Tubal Cannulation

Proximal tubal occlusion is often amenable to direct techniques. If diagnosed at the time of hysterosalpingography (HSG), consideration is given to performing concurrent selective salpingography. With this, a catheter is placed such that it wedges within the tubal ostium. This allows significant hydrostatic pressure to be applied to the tube. Such pressure will likely overcome most instances of tubal spasm or plugging by mucus or debris. If tubal patency cannot be reestablished, an inner catheter with guide wire is used to cannulate the tube. This creates patency of isolated short segmental scarring in most instances. Scarring of a longer segment or luminal obliteration, however, is not amenable to correction with tubal cannulation. In these women, surgical segmental resection with reanastomosis or IVF may be considered.

Tubal Reconstruction

Proximal Tubal Obstruction. Tubal obstruction not amenable to treatment with selective salpingography has traditionally been treated surgically, and options include hysteroscopic cannulation, surgical reanastomosis, and neosalpingostomy. Although success rates of ART have risen considerably, reproductive surgery remains an important option or complement to ART for many couples.

Some types of tubal blockage have a much better prognosis with surgical therapy than others. For example, hysteroscopic cannulation of fallopian tubes can treat some types of proximal obstruction

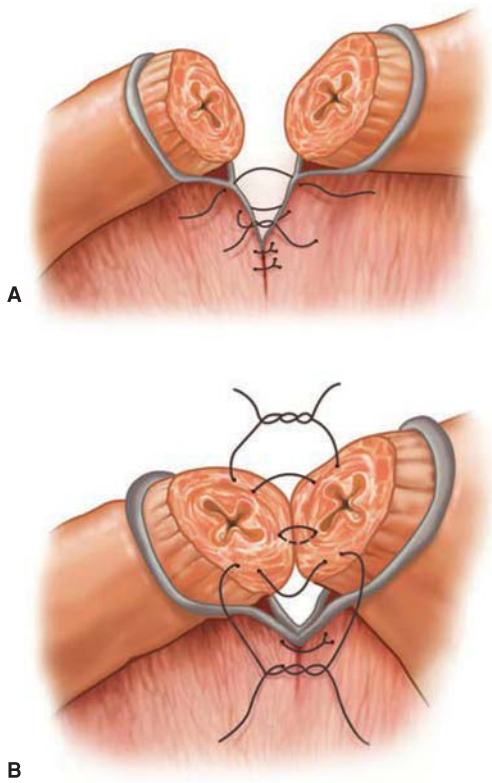

FIGURE 21-6 Surgical reanastomosis of fallopian tube segments. The scarred portion of the tube is sharply excised until nonfibrotic tubal tissues are reached. **A.** The mesosalpinx is re-approximated with interrupted stitches using 6-0 delayed-absorbable suture. **B.** The tubal muscularis is reapproximated with single stitches in each quadrant using 7-0 delayed-absorbable suture. Tubal serosa is closed with interrupted or running 6-0 delayed-absorbable suture.

in a fashion similar to selective salpingography (Section 44-17, p. 1067). Hysteroscopic cannulation is best performed with concurrent laparoscopy to verify distal tubal patency.

Proximal obstruction not amenable to cannulation techniques can be treated with segmental resection and reanastomosis (Fig. 21-6). In most cases, this can be done as an outpatient procedure through a minilaparotomy incision. However, obstruction extending into the interstitial portion of the tube is more technically challenging to repair and more prone to repeated obstruction postoperatively. Therefore, proximal occlusion extending to the interstitial segment that cannot be treated with cannulation is best treated in most instances with IVF.

Options for proximal and midtubal occlusion resulting from prior sterilization are either tubal reanastomosis or IVF. From a patient perspective, outpatient tubal reanastomosis avoids ovarian stimulation and its higher risk for multifetal gestation and provides an ability to conceive normally. In general, although the monthly probability of pregnancy following tubal reversal is likely lower than that for age-matched controls without prior sterilization, the cumulative chance of pregnancy is high. However, IVF is strongly considered if other fertility factors are present or the type of sterilization performed does not permit reconstruction. For example, in cases of sterilization completed by fimbriectomy, neosalpingostomy can be corrective. However, the probability of pregnancy is lower, and IVF is considered. Importantly, the risk of subsequent ectopic pregnancy following reanastomosis for midtubal occlusion is 3 to 5 percent (Gordts, 2009).

The "reversibility" of sterilization can generally be determined by review of the operative report and also the pathology report if the procedure involved segmental resection. If operative records are unavailable or suggest that reanastomosis may not be feasible, laparoscopy is performed prior to laparotomy to assess chances of surgical success.

Outpatient reversal of sterilization is most commonly done by minilaparotomy. Incision size typically ranges from 3 to 6 cm depending on a patient's weight and anatomy. Some surgeons are able to complete some of these procedures laparoscopically. Robotic control may be helpful for this but may increase operating time and expense.

Distal Tubal Obstruction. Following pelvic inflammatory disorders, normal fimbrial anatomy may be destroyed, or fimbria may be encased by adnexal adhesions. In these cases, neosalpingostomy can be performed at minilaparotomy or laparoscopy (Fig. 21-7). However, women desiring neosalpingostomy for treatment of distal occlusion are counseled that the risk of ectopic pregnancy is high, the likelihood of pregnancy is 50 percent or lower, and postoperative reocclusion is common (Bayrak, 2006). Moreover, hydrosalpinges that are dilated more than 3 cm in diameter, that are associated with significant adnexal adhesions, or that display an obviously attenuated endosalpinx yield a poor prognosis. These tubes are best treated by salpingectomy. If both tubes are affected, bilateral salpingectomy is recommended prior to proceeding with IVF. This stems from data showing women with hydrosalpinges undergoing IVF have approximately half the pregnancy rate of other women with unaffected tubes (American Society for Reproductive Medicine, 2015c).

Uterine Factors

Various uterine factors have been implicated in infertility and include adenomyosis, leiomyomas, endometrial polyps, and intrauterine adhesions. Müllerian anomalies, especially intrauterine septum or segmental agenesis, can increase rates of

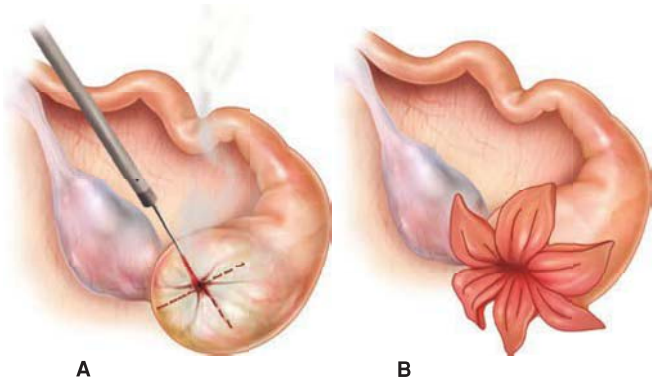

FIGURE 21-7 Neosalpingostomy. **A.** The distal end of the clubbed fallopian tube is opened sharply or with electric or laser energy. **B.** The endosalpinx is everted using Cuff or Bruhat technique.

infertility or pregnancy complications. These congenital abnormalities are described fully in Chapter 19 (p. 419). Mechanisms of infertility with these factors have not been clearly elucidated. However, the end result is diminished endometrial receptivity and reduced likelihood of embryo implantation.

Leiomyomas

These are common benign tumors of the uterus and have been associated with infertility in some women (Chap. 9, p. 205). Retrospective studies have suggested a benefit from surgically removing certain tumors to increase efficacy of both natural and assisted conception.

No randomized trials clearly demonstrate that myomectomy improves fertility (Metwally, 2012). However, in view of the many retrospective observational studies that suggest a benefit, myomectomy can be offered to well-selected infertile women, especially if tumors are large or impinge on the endometrial cavity. Leiomyomas can be removed using hysteroscopy, laparoscopy, or laparotomy, and approach selection is discussed in Chapter 9 (p. 210). Currently, for predominantly intramural or subserosal myomas, no studies validate one method compared with another in terms of efficacy. For intracavitary myomas, no data show one surgical approach to be most effective for fertility, and thus the least invasive hysteroscopic approach is reasonable. In general, clinical judgment should determine the most appropriate technique from the standpoint of safety, restoration of normal uterine anatomy, and speed of recovery.

Endometrial Polyps

These soft, fleshy endometrial growths are commonly diagnosed during infertility evaluation. Several studies suggest good pregnancy rates following polypectomy, although the mechanism by which polyps impair fertility is not established.

For management, one prospective trial of 204 women with polyps and with an additionally diagnosed cervical factor, male factor, or unexplained infertility provides some clear guidance. In this trial, women were randomly assigned to one of two groups prior to treatment with intrauterine insemination (IUI) (Pérez-Medina, 2005). The first group underwent polypectomy. The second underwent only hysteroscopic biopsy of the polyp to obtain histologic confirmation. All patients were managed expectantly for three cycles prior to proceeding with up to four cycles of IUI. The pregnancy rate in the polypectomy group was more than twice as high regardless of initial polyp size (Table 21-4). These data suggest that endometrial polyps can significantly impair infertility treatment outcome. Thus, hysteroscopic polypectomy in all infertile patients if a polyp is identified seems reasonable (Section 44-13, p. 1056).

TABLE 21-4. Number and Percentage of Pregnancies after Hysteroscopic Polypectomy ($n = 204$)

Intrauterine Adhesions

Adhesions within the endometrial cavity, also called *synechiae*, can range from asymptomatic small bands to complete or near complete obliteration of the endometrial cavity. If amenorrhea or hypomenorrhea result, the condition is termed *Asherman syndrome* (Chap. 17, p. 374).

Treatment involves surgical adhesiolysis to restore normal uterine cavity size and configuration. Dilation and curettage (D & C) and abdominal approaches were previously used. However, with the advantages of hysteroscopy, the role of these other techniques has been minimized.

Hysteroscopic adhesion resection may range from simple lysis of a small band to extensive adhesiolysis of dense intrauterine adhesions using scissors, electrosurgical cutting, or laser energy (Section 44-18, p. 1069). However, women whose uterine fundus is completely obscured and those with a markedly narrowed, fibrotic cavity present the greatest therapeutic challenge. Several techniques are described for these difficult cases, but outcome is far worse than in patients with small band adhesions. In those women with severe Asherman syndrome that is not amenable to reconstructive surgery, gestational carrier surrogacy or uterine transplantation is a valuable option (p. 466).

Peritoneal Disease

Endometriosis

This condition and its effects on infertility are extensively discussed in Chapter 11 (p. 247). In women with minimal or mild disease, evidence supporting lesion ablation is limited and use of empiric general fertility boosting procedures such as ART or superovulation combined with IUI is reasonable. These treatments have been validated to increase fecundity in women with stage I and II disease (Table 21-5) (Guzick, 1999).

Moderate and severe endometriosis results in distortion of anatomic relationships of reproductive organs. In many cases, surgical treatment may improve anatomy, and pregnancy can result (American Society for Reproductive Medicine, 2012). Unfortunately, advanced disease may prevent adequate restoration of pelvic anatomy. Therefore, a surgeon's operative findings and anticipated surgical results guide postoperative strategy. If satisfactory surgical outcome is achieved, spontaneous conception can be attempted for 6 to 12 months prior to considering other options such as IVF. Notably, endometriosis in some cases may recur quickly, and unnecessary delay in attempting pregnancy postoperatively is not advised.

In women with advanced endometriosis, several studies suggest that long-term treatment with GnRH agonists before initiation of a cycle may improve fecundity (Dicker, 1992; Surrey, 2002). Currently, however, this treatment strategy is not universally accepted.

If endometriomas are noted, surgical options include cyst drainage, drainage followed by cyst wall ablation, or cyst excision. These three procedures can be performed laparoscopically in nearly all circumstances given adequate surgeon experience. Simple drainage minimizes ovarian destruction but commonly

TABLE 21-5. Cycle Fecundity with Stage I or II Endometriosis Compared with Unexplained Infertility

results in rapid cyst recurrence. One histologic study demonstrated that a mean of 60 percent of the cyst wall surface area (range of 10 to 98 percent) was lined by endometrium to a depth of 0.6 mm (Muzii, 2007). Thus, drainage and ablation may not destroy all endometrium to this depth. Moreover, this approach is associated with significant risk of cyst recurrence and thermal damage to the ovary. For these reasons, laparoscopic excision of the cyst wall by a stripping technique is considered optimal treatment for most endometriomas (Section 44-5, p. 1030). Hart and coworkers (2008) compared ablative surgery and cyst excision. With excision, they noted more favorable rates of diminished pain, cyst recurrence, and spontaneous pregnancy. However, excision is inevitably accompanied by removal of normal ovarian tissue and often leads to decreased ovarian volume and diminished ovarian reserve (Almog, 2010; Exacoustos, 2004; Ragni, 2005).

Endometrioma recurrence is common. But, surgery for a recurrent endometrioma appears to be even more harmful to the ovarian reserve than primary surgery (Muzii, 2015). Thus, further ovarian surgery is individualized (American College of Obstetricians and Gynecologists, 2018a). If there is confidence in the diagnosis, it may be prudent in some cases to avoid surgery entirely when future fertility is desired.

Pelvic Adhesions

Pelvic adhesions may result from endometriosis, prior surgery, or pelvic infection and often vary in their density and vascularity. Adhesions may impair fertility by distorting adnexal anatomy and by interfering with gamete and embryo transport, even in the absence of tubal disease.

Surgical lysis may restore pelvic anatomy in some cases, but adhesions may recur, especially if they are dense and vascular. Adherence to microsurgical principles and minimally invasive surgery may help decrease adhesion formation. Although numerous adjuvants, such as adhesion barriers, have been used to reduce the risk of postoperative adhesion formation, currently none has been validated to improve fecundity (American Society for Reproductive Medicine, 2013b).

Among infertile women with adnexal adhesions, pregnancy rates after adhesiolysis are 32 percent at 12 months and 45 percent at 24 months of surveillance. These rates can be compared with 11 percent at 12 months and 16 percent at 24 months in those left untreated (Tulandi, 1990). As with severe endometriosis, clinical judgment regarding operative findings and results of surgery should guide the strategy postoperatively. IVF is the best option for those with a poor prognosis for normal anatomy restoration.

CORRECTION OF CERVICAL ABNORMALITIES

In response to follicular estradiol production, the cervix should produce abundant thin mucus. If present, this mucus acts as a conduit and functional reservoir for sperm. Accordingly, inadequate cervical mucus impairs sperm transport to the upper female reproductive tract.

Causes of abnormal or deficient mucus include infection, prior cervical surgery, use of antiestrogens (e.g., clomiphene citrate) for ovulation induction, and sperm antibodies. However, many women with decreased or hostile mucus have no history of predisposing factors.

Examination of cervical mucus may reveal gross evidence of chronic cervicitis that deserves treatment. Doxycycline, 100 mg orally twice daily for 10 days, is an appropriate therapy. In those with decreased mucus volume, treatments include short-term supplementation with exogenous estrogen, such as ethinyl estradiol. This can be coupled with oral doses of the mucolytic expectorant guaifenesin, which thins the mucus. However, the value of estrogen plus guaifenesin has not been confirmed. Moreover, exogenous estrogens could have a negative effect on follicular development and ovarian function.

For these reasons, most clinicians treat noninfectious, suspected cervical mucus abnormalities with IUI. Although this

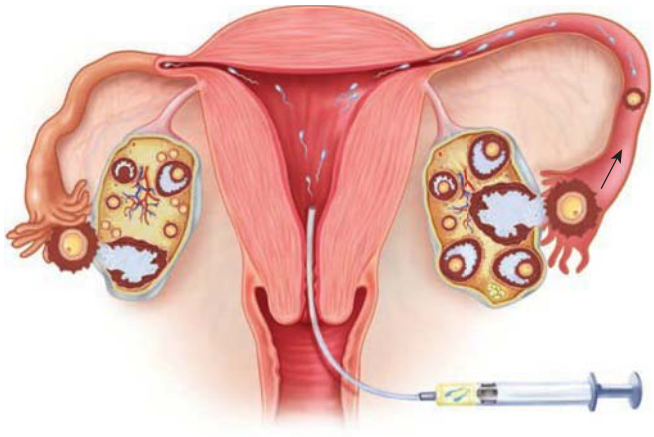

FIGURE 21-8 Intrauterine insemination (IUI). Prior to IUI, partner or donor sperm is washed and concentrated. IUI is usually combined with superovulation, and signs of impending ovulation are monitored with transvaginal sonography. At the time of suspected ovulation, a long, thin catheter is threaded through the cervical os and into the endometrial cavity. A syringe containing the sperm concentrate is attached to the catheter's distal end, and the sperm sample is injected into the endometrial cavity.

approach also has not been validated with randomized trials, the theoretical basis for this approach seems sound (Helmerhorst, 2005). Additionally, IUI is effective for treatment of unexplained infertility. As a result, many clinicians forgo cervical mucus testing and proceed directly with IUI treatments in the absence of tubal disease (Fig. 21-8).

CORRECTION OF MALE INFERTILITY

Male infertility has numerous causes and may include various sperm or semen volume abnormalities that are described subsequently. Accordingly, therapy should be planned only after thorough evaluation (Chap. 20, p. 442). In the absence of identifiable correctable cause, it is appropriate to offer IUI or ART as treatment options. The choice of whether to proceed initially with IUI therapies as opposed to the more intensive and expensive ART treatments depends on several factors. These include duration of infertility, age of the female, and history of prior treatments. If ART is considered for male factor infertility, intracytoplasmic sperm injection (ICSI) is typically selected rather than traditional IVF (Fig. 21-9).

FIGURE 21-9 Photomicrograph of intracytoplasmic sperm injection.

Abnormal Semen Volume

Aspermia is characterized by a complete lack of semen and results from failure to ejaculate. The physiology of ejaculation includes emission of sperm with accessory gland fluid into the urethra, simultaneous closure of the urethral sphincters, and forceful ejaculation of semen through the urethra. Emission and closure of the bladder neck are primarily alpha-adrenergically mediated thoracolumbar sympathetic reflex events with supraspinal modulation. Ejaculation is a sacral spinal reflex mediated by the pudendal nerve.

Anejaculation or anorgasmia is not rare and may stem from psychogenic factors, organic erectile dysfunction, or impaired parasympathetic sacral spinal reflex. Appropriate treatments depend on the cause and can include psychologic counseling or erectile dysfunction treatment with sildenafil citrate (Viagra) or other similar medication. Vibratory stimulation may also be effective in some instances. Electroejaculation is an invasive procedure and is generally used for men with spinal cord injuries who are unresponsive to the therapies above.

Men who always achieve orgasm but never experience prograde ejaculation or have a greatly reduced prograde volume typically have retrograde ejaculation. In these cases, oral pseudoephedrine or another alpha-adrenergic agent to aid bladder neck closure is suitable. However, for many, pharmacologic methods are ineffective, and IUI may be performed using sperm processed from a voided urine specimen collected after ejaculation. Oral sodium bicarbonate may be used prior to sperm collection to reduce the risk of harm to the sperm from a low urinary pH.

A few men who achieve orgasm, but not prograde ejaculation, have failure of emission. A trial of sympathomimetic agents is reasonable in these individuals as well, although pharmacologic therapies generally provide limited success. Alternatively, testicular or epididymal extraction of sperm via aspiration or biopsy may be used in cases refractory to medication. As with electroejaculation, this technique recovers a limited number of viable sperm and is best suited for use with ICSI.

Hypospermia, that is, low semen volume (<2 mL), impairs sperm transport into cervical mucus and can be associated with decreased sperm density or motility. Retrograde ejaculation may underlie this condition, and its treatment follows that just described for aspermia.

Alternatively, hypospermia may follow partial or complete ejaculatory duct obstruction. In these cases, transurethral excision of the ejaculatory duct obstruction has resulted in marked semen parameter improvement, and pregnancies have been achieved. However, couples are counseled that postoperative complete obstruction of the ejaculatory ducts is not rare. Thus, consideration is given to cryopreservation of sperm prior to surgical attempts in those individuals with partial obstruction.

Abnormal Sperm Count

Azoospermia is characterized by the total absence of sperm in semen. This may result from male reproductive tract obstruction or from nonobstructive causes.

Obstructive azoospermia, especially resulting from prior vasectomy or ejaculatory duct obstruction, may be amenable to surgical treatment. However, congenital bilateral absence of the vas deferens (CBAVD) is a common cause of azoospermia and unfortunately is not treatable surgically. In such candidates, testicular sperm extraction (TESE) may be performed in conjunction with ICSI.

Nonobstructive azoospermia may be caused by a karyotypic abnormality such as Klinefelter syndrome (47,XXY) or balanced translocation; deletion of a small portion of the Y chromosome; testicular failure; or unexplained causes. In many cases, TESE may be combined effectively with ICSI in those with Klinefelter syndrome and Y microdeletion of the AZFc region. However, in men with Y microdeletion in the AZFa or AZFb region, this ART combination has been ineffective (Choi, 2004).

Oligozoospermia is diagnosed if fewer than 15 million sperm are present per milliliter of semen. Causes are varied and include hormonal, genetic, environmental (including medications), and unexplained causes. Additionally, an obstructive cause, especially ejaculatory duct obstruction, should be considered if oligozoospermia accompanies low semen volume. If severe oligozoospermia (<5 to 10 million sperm/mL) is noted, an evaluation similar to that for azoospermia is indicated.

Oligozoospermia without decreased sperm motility not uncommonly reflects hypogonadotropic hypogonadism. In general, hypogonadotropic hypogonadism is best treated with FSH and hCG administered to the male. Alternatively, CC or aromatase inhibitors, although not FDA-approved treatment for this indication, may be considered for some males, especially if obesity and elevated serum estradiol levels are present. Spermatogenesis is a long process lasting approximately 100 days. Thus, several months may be required to identify significant improvements in sperm density with either treatment.

Environmental factors such as excessive exposure to high temperatures should be investigated. Drug and medication history also is obtained. If an environmental factor is identified, correction may improve sperm numbers (Chap. 20, p. 431).

Abnormal Sperm Motility or Morphology

Asthenospermia, that is, decreased sperm motility, may be seen alone or in combination with oligozoospermia or other abnormal semen parameters. In general, asthenospermia does not respond to directed treatments. Expectant management may be considered especially if the duration of infertility is short and maternal age is younger than 35 years. For treatment, IUI and ICSI are preferred, although IUI is generally not successful in severe cases (Tan, 2014). If fewer than 1 million motile sperm are available for insemination following semen processing or the couple has experienced more than 5 years of infertility, ICSI is considered as initial therapy (Ludwig, 2005).

Teratozoospermia or abnormal sperm morphology is most often seen in conjunction with oligospermia, asthenospermia, and oligoasthenospermia. Directed treatments for teratozoospermia are not available, and therapy options include IUI and ART. Because teratozoospermia may commonly be accompanied by sperm function defects that may impair fertilization, ICSI is considered if ART is selected.

Varicocele

This results from dilation of the pampiniform plexus of the spermatic vein and is usually left-sided (Fig. 20-2, p. 431). Traditional treatment is surgical ligation of the internal spermatic vein. Of options, retroperitoneal high ligation and trans-inguinal ligation are the most frequently performed. More recently, interventional radiographic techniques that selectively catheterize and embolize the internal spermatic vein with sclerosing solutions, tissue adhesives, or detachable balloons or coils are alternatives. Despite the widespread application of varicocele treatments, insufficient evidence demonstrates conception success with the treatment of a clinical varicocele in couples with male subfertility (Evers, 2003).

UNEXPLAINED INFERTILITY

This may represent one of the most common infertility diagnoses, and its reported prevalence reaches up to 30 percent (Dodson, 1987). The diagnosis is highly subjective and depends on the diagnostic tests performed or omitted and on their quality. Paradoxically, a diagnosis of unexplained infertility, therefore, will more often be reached if the evaluation is incomplete or poor quality (Gleicher, 2006). Nevertheless, an unexplained infertility diagnosis cannot, by definition, be directly treated. Expectant management may be considered especially with infertility of short duration and with relatively young maternal age. However, if treatment is desired, IUI, superovulation, and ART are empiric appropriate interventions to consider.

INTRAUTERINE INSEMINATION

This technique uses a thin flexible catheter to place a prepared semen sample into the uterine cavity. First, motile, morphologically normal spermatozoa are separated from dead sperm, leukocytes, and seminal plasma. This highly motile fraction is then inserted transcervically near the anticipated time of ovulation. Intrauterine insemination can be performed with or without superovulation and is appropriate therapy for treatment of cervical factors, mild and moderate male factors, and unexplained infertility.

If performed for cervical factors, IUI timed by urine LH surge is an initial strategy that achieves reasonable pregnancy rates of up to 11 percent per cycle (Steures, 2004). Although this rate is lower than that seen with superovulation combined with IUI, the side effects and expense of superovulation are avoided.

In contrast, for unexplained infertility and for male factors, IUI is most commonly performed with superovulation. A combination of CC plus IUI was evaluated against observation for unexplained infertility by Deaton and coworkers (1990) in one randomized trial. The treatment group had a significantly higher pregnancy rate (9.5 percent) compared with the observation cohort (3.3 percent). For unexplained infertility, gonadotropin treatment (FSH or hMG) alone increases the pregnancy rate, but the benefit is markedly improved with the addition

of IUI (Guzick, 1999). Aromatase inhibitors do not appear to be as efficacious for IUI as conventional CC or gonadotropin treatments for unexplained infertility (Diamond, 2015).

ASSISTED REPRODUCTIVE TECHNOLOGY

ART describes clinical and laboratory techniques used to achieve pregnancy in infertile couples for whom direct corrections of underlying causes are not feasible. In principle, IUI meets this definition. By convention, however, ART procedures are those that at some point require extraction and isolation of an oocyte as described in the following paragraphs.

In Vitro Fertilization

During IVF, mature oocytes from stimulated ovaries are retrieved transvaginally with sonographic guidance (Fig. 21-10). Sperm and ova are then combined in vitro to prompt fertilization (Fig. 21-11). If successful, viable embryos are transferred transcervically into the endometrial cavity using sonographic

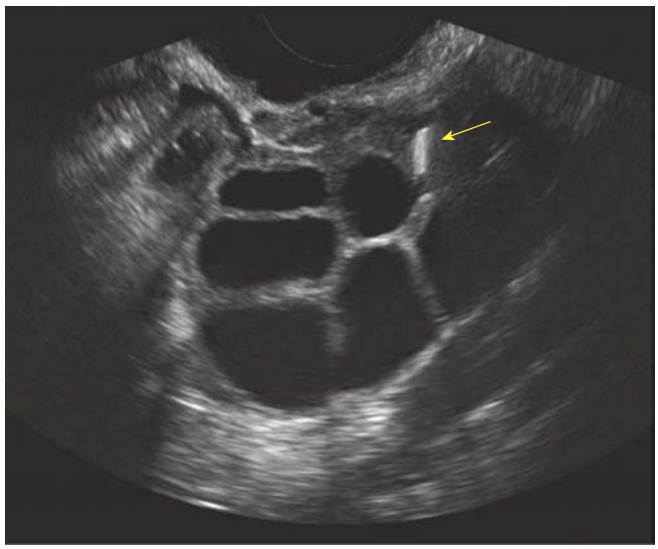

FIGURE 21-10 Transabdominal sonogram demonstrates transvaginal oocyte retrieval. The needle is seen in the upper right portion of the image as a hyperechoic line (*arrow*) entering a mature follicle.

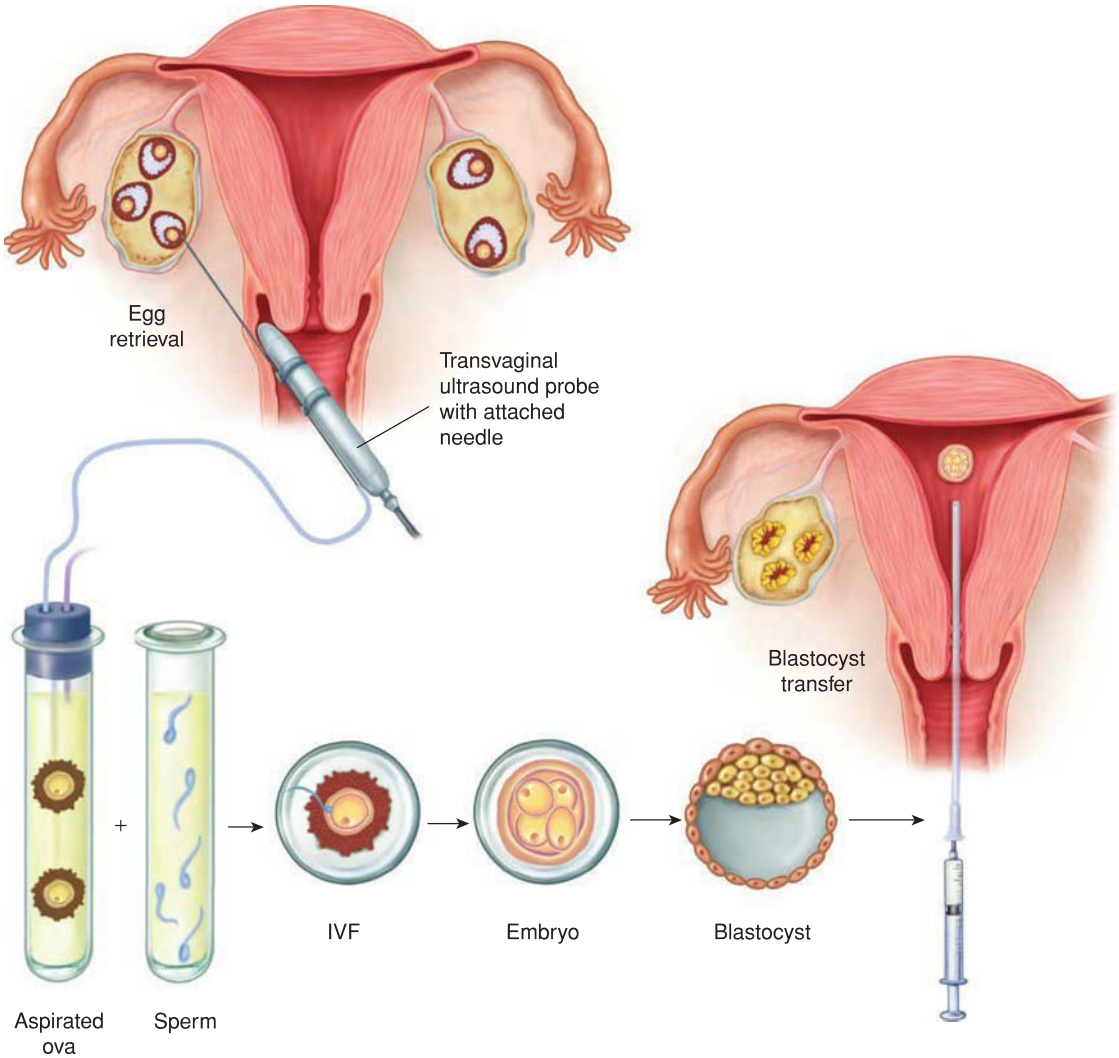

FIGURE 21-11 In vitro fertilization (IVF). Controlled ovarian stimulation is achieved with one of the protocols displayed in Figure 21-2, and follicle maturation is monitored over several days sonographically. Near ovulation, a transvaginal approach is used to harvest eggs from the ovaries (see Fig. 21-10). These oocytes are fertilized in vitro, and fertilized eggs develop to the blastocyst stage. Blastocysts are then drawn up into a syringe and delivered into the endometrial cavity under sonographic guidance.

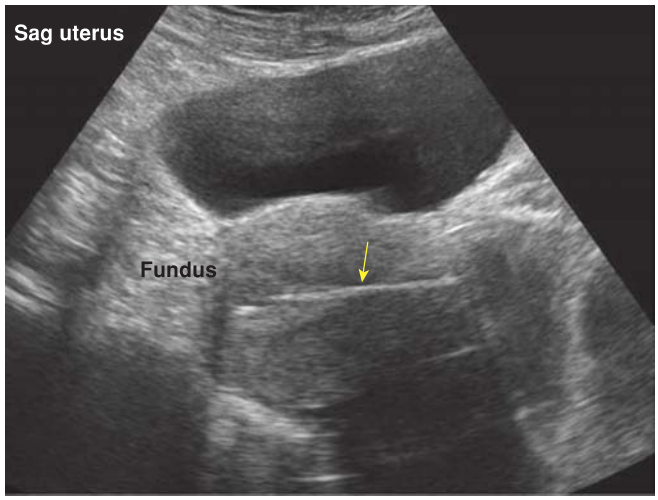

FIGURE 21-12 Embryo transfer performed using abdominal sonographic guidance for proper placement. Catheter (*arrow*) is seen within the endometrial cavity.

guidance (Fig. 21-12). Discussed earlier, prior to proceeding with IVF, hydrosalpinges are removed or tubes are interrupted to help raise implantation rates and lower miscarriage risk (p. 460).

Similar to IUI, substantial benefit is achieved using controlled ovarian stimulation prior to egg retrieval. Many ova are genetically or functionally abnormal. Thus, exposure of several ova to sperm results in a greater chance of a healthy embryo. Most often, a GnRH agonist is coupled with gonadotropins (FSH or hMG). These agonists prevent the possibility of spontaneous LH surge and ovulation prior to egg retrieval. Optimally, 10 to 20 ova are harvested, and from these, one healthy embryo is ideally transferred back to the uterus.

Unfortunately, methods to determine embryo health are imperfect. To maximize the probability of pregnancy, more than one embryo is commonly transferred to older women, which raises the multifetal gestation risk. However, advances in culture conditions now permit embryos to be cultured to the blastocyst stage. This allows transfer of fewer embryos yet maintains high pregnancy rates (Langley, 2001).

Intracytoplasmic Sperm Injection

This variation of IVF is most applicable to male factor infertility. During the micromanipulation technique of ICSI, cumulus cells surrounding an ovum are enzymatically digested, and a single sperm is directly injected through the zona pellucida and oocyte cell membrane (see Fig. 21-9). Pregnancy rates with ICSI are comparable with those achieved with IVF for other causes of infertility. For azoospermic men, ICSI has made pregnancy in their partners possible. In these cases, sperm are mechanically extracted from the testicle or epididymis.

Gestational Carrier Surrogacy

This variation of IVF places a fertilized egg into the uterus of a surrogate rather than into the "intended mother." Indications are varied, and this approach may be appropriate for women with uncorrectable uterine factors, for those in whom pregnancy would pose significant health risks, and for those with repetitive unexplained miscarriage.

Gestational carrier surrogacy has legal and psychosocial issues. In most states, a surrogate is the legal parent, and adoption must be completed after birth to give the intended mother her parental rights. However, a few states have adopted specific laws that extend protection to the intended parents.

Although still considered experimental, uterus transplantation is an alternative to gestational carrier surrogacy for women with absolute uterine factor infertility. Examples include uterine agenesis, prior hysterectomy, obliterating intrauterine adhesions, and distorting leiomyomas. In 2015, the first birth following uterine transplant was reported (Brännström, 2015). Postoperative immunosuppressive therapy and close monitoring for signs of rejection are essential. Attempts at pregnancy should be delayed until it is reasonably certain that the surgery has been successful. Initially, no attempts to achieve pregnancy were made for 12 months. IVF is required in all cases (Brännström, 2018). More recently, some transplant centers have allowed patients to undergo IVF at 6 months or earlier following surgery. Currently, uterine transplantation is done following institutional review and under strict protocols by expert transplant surgeons. A uterine transplant registry is currently being developed to follow long-term outcomes.

Egg Donation

This may be employed in cases of infertility associated with ovarian failure or diminished ovarian reserve. Fertile women whose offspring would be at risk for maternally transmitted genetic disease are other candidates. Egg donors may be known to the recipient couple or more commonly are anonymous young women recruited by an agency or IVF center.

Egg donation can be performed using "fresh" oocytes or cryopreserved eggs. Fresh egg donation cycles require synchronization of the recipient's endometrium with egg development in the donor.

To accomplish this, the egg donor completes one of the superovulation protocols outlined in Figure 21-2. Concurrently, if a recipient is not menopausal, GnRH agonists are administered to her to suppress gonadotropin production. This allows a scheduled priming of her endometrium with estrogen and progesterone. Following gonadotropin suppression, exogenous estrogen is given to the recipient. This estrogen administration begins just prior to the start of gonadotropin administration to the egg donor. After the donor receives hCG to allow the final stages of follicle and egg maturation, the recipient begins progesterone to prepare her endometrium. In the recipient, estrogen and progesterone are typically continued until late in the first trimester when placental production of these hormones is deemed to be adequate.

Gamete or Zygote Intrafallopian Transfer

Gamete intrafallopian transfer (GIFT) is similar to IVF in that egg retrieval is performed after controlled ovarian stimulation. Unlike IVF, however, fertilization and early embryo development do not take place in the laboratory. Eggs and sperm are placed via catheter through the fimbria and deposited directly into the

oviduct. This transfer of gametes is most commonly performed at laparoscopy. Like IUI, GIFT is most applicable for unexplained infertility and is not considered for tubal factor causes.

This technique was most popular in the late 1980s. However, as laboratory techniques have improved, IVF has largely replaced GIFT. In general, GIFT is more invasive, provides less diagnostic information, and requires transfer of more than two eggs for optimal pregnancy chances, which raises risks for higher-order multifetal gestation. Thus, the major current indication for GIFT is to avoid the religious or ethical concerns that some patients may have with fertilization taking place outside the body.

Zygote intrafallopian transfer (ZIFT) is a variant of IVF with similarities to GIFT. Zygote transfer is not performed directly into the uterine cavity but rather into the fallopian tube at laparoscopy. If the transfer is completed after a zygote has begun to divide, the procedure is more accurately termed *tubal embryo transfer (TET)*. Although a normal fallopian tube may provide a superior environment for the early-stage embryo, improved laboratory culture methods has lessened this advantage. Accordingly, ZIFT currently is considered most appropriately in the rare case in which transcervical transfer during IVF is not technically feasible.

Intravaginal Culture

Fertilization of eggs and culture of embryos has generally required a complex and costly laboratory infrastructure to optimize the environment for the gametes/embryos. The modern IVF laboratory requires expensive air filtration systems as the embryo has no lung, kidney, or liver to act as filters (Mortimer, 2005). Incubators can provide temperature control and an optimal mix of oxygen (O_2), carbon dioxide (CO_2), and nitrogen. Those specifically designed for IVF are complex electromechanical devices and thus are prone to drift or failure. These systems require alarms, daily quality control checks, and around-the-clock monitoring.

Intravaginal culture (IVC) was proposed more than 30 years ago as a means to simplify and increase access to reproductive care (Ranoux, 1988). Initial studies, using improvised IVC devices, demonstrated that the vagina could provide an appropriate temperature and gas environment. However, adoption was limited due to instances of vaginal bacterial contamination and other device constraints.

More recently, a device specifically designed for IVC (INVOcell) has been approved by the FDA. This device is composed of polystyrene and allows maintenance of an appropriate low O_2, high CO_2 environment (Fig. 21-13). A recent prospective

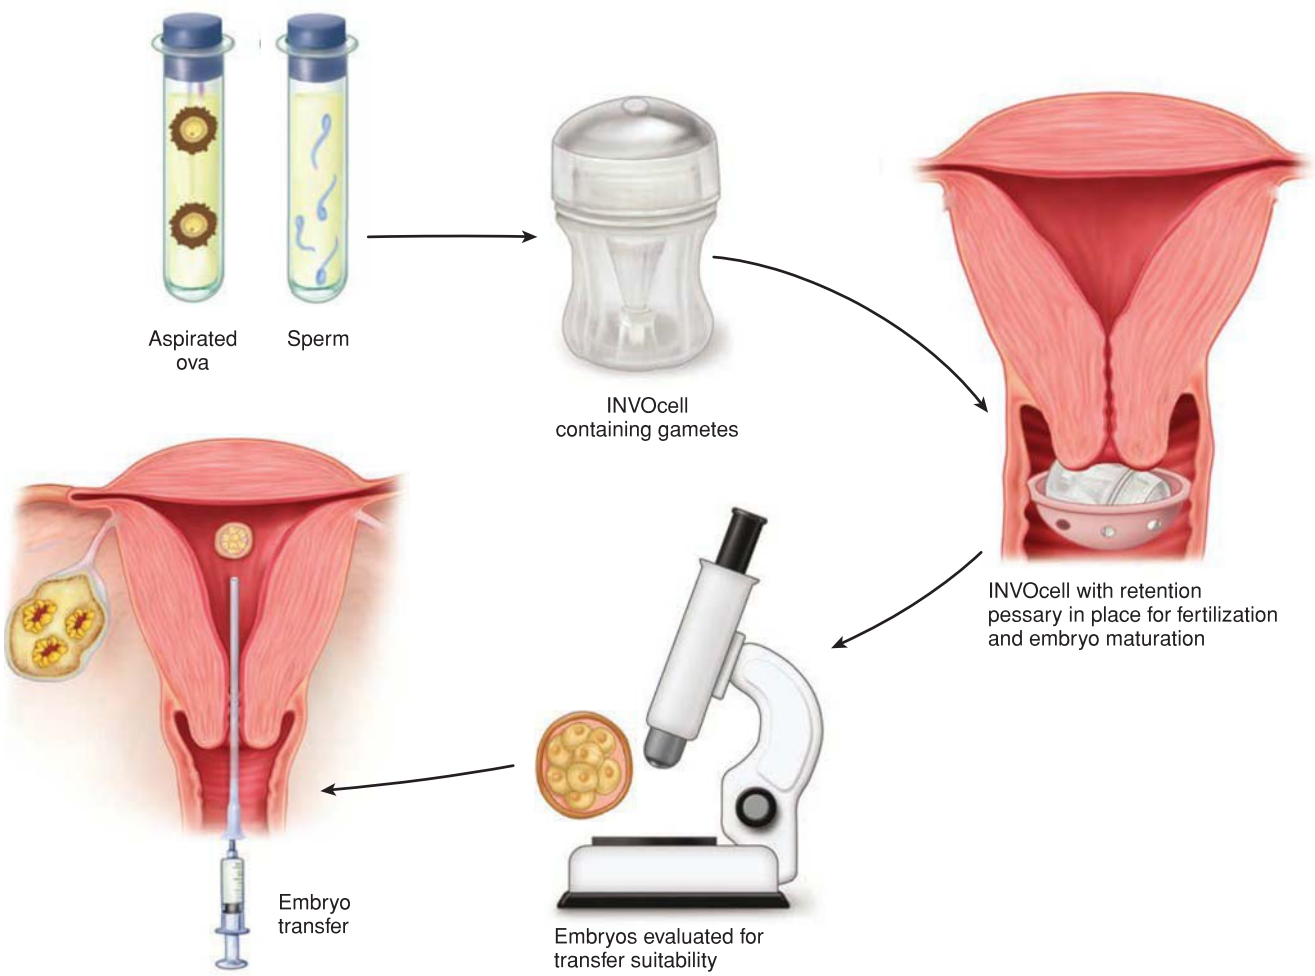

FIGURE 21-13 With intravaginal culture (IVC), fertilization and embryo maturation occur in vivo. First, superovulation is induced, and ova are harvested. These are then combined with sperm in the INVOcell device for fertilization within the vaginal. After several days to allow embryo maturation, the INVOcell device is removed, and embryos are inspected. One of those deemed suitable is then transferred into the endometrial cavity.

randomized trial has demonstrated live birth rates with INVOcell similar to conventional laboratory incubators when used for fertilization and extended embryo culture (day 5 blastocyst). (Doody, 2016). Further investigation will determine whether IVC will broaden access to ART care.

Embryo, Oocyte, or Ovarian Tissue Cryopreservation

With IVF, many eggs are retrieved to ultimately produce one to three healthy embryos for transfer. This frequently leads to extra embryos. Successful freezing and thawing of embryos has been possible for two decades. Moreover, advances in cryoprotectants and techniques have improved survival rates of embryos frozen at various developmental stages. With cryopreservation, these supernumerary embryos can yield pregnancies later, obviating the need for repeated ovarian stimulation and egg retrieval. For some patients, cryopreservation of all embryos avoids fresh transfer. Instead, later transfer can allow improved synchrony between the embryo and the endometrium for higher pregnancy rates (Doody, 2014).

Cryopreservation of unfertilized eggs had previously posed significant technical hurdles. These challenges have been largely overcome by ultrarapid freezing techniques (vitrification), and oocyte cryopreservation is no longer considered experimental. Egg freezing is useful for women facing gonadotoxic chemotherapy. This technique also provides greater timing flexibility to circumvent cycle synchronization during egg donation. As success improves, oocyte cryopreservation may assist women desiring to delay childbearing, although data are lacking regarding its efficacy in this patient population. Careful counseling is needed with regard to age- and clinic-specific success rates (American Society for Reproductive Medicine, 2014).

Distinct from oocyte freezing, ovarian tissue cryopreservation is another fertility-preserving option. Candidates are patients who must urgently undergo potentially gonadotoxic treatments. With this method, one or both ovaries or ovarian cortex tissue is removed during laparoscopy or minilaparotomy. Postoperatively, the ovarian cortex is cut into small tissue slivers measuring 0.3- to 2-mm thick and cryopreserved. Ovarian tissue cryopreservation by both slow freezing and vitrification has been described. Successful pregnancies have been achieved following autologous transplantation of thawed cortical tissue into a pelvic site such as a contralateral ovary or pelvic sidewall. Some pregnancies have been achieved without further intervention, whereas others have required ART. Safety concerns include the risk for reintroducing a malignancy following transplantation. This risk may be greatest with blood-borne cancers such as leukemia. Although promising, this procedure is currently considered experimental (American Society for Reproductive Medicine, 2014).

In Vitro Maturation

This technique has been used to achieve pregnancy by aspirating antral follicles from unstimulated ovaries and culturing these immature oocytes to allow resumption and completion of meiosis in vitro. In vitro maturation (IVM) may be useful in patients with PCOS in whom stimulation poses a significant risk of OHSS. Recent data suggest that success rates with standard IVF remain superior to those with IVM (Walls, 2015). Additionally, long-term outcomes are unknown, and IVM is deemed experimental (American Society for Reproductive Medicine, 2013a). In the future, refinement of this technique may make possible maturation of ova from preantral follicles. This could potentially allow preservation of fertility potential but without the need for subsequent autologous transplantation for women in whom gonadotoxic chemotherapy is required.

Preimplantation Genetic Testing

These laboratory techniques identify genetic abnormalities in eggs or embryos prior to their transfer. Preimplantation genetic testing (PGT) can analyze the DNA from oocytes (polar bodies) or embryos (cleavage stage or blastocyst) for determining genetic abnormalities or for human leukocyte antigen (HLA) typing. Options include PGT for aneuploidies (PGT-A), PGT for monogenic/single-gene defects (PGT-M), and PGT for chromosomal structural rearrangements (PGT-SR), such as balanced translocations (Zegers-Hochschild, 2017). Thus, risk for transmission of heritable disease is a well-established indication for PGT. In contrast, *PGT-A* aims to identify embryonic aneuploidy resulting from gamete meiotic errors. Its proposed indications include recurrent miscarriage, advanced maternal age, and multiple failed IVF cycles.

PGT is no longer considered experimental, and newly developed methods for genetic analysis will likely broaden its application (Society for Assisted Reproductive Technology, 2008). During PGT, cells can be removed from a developing pregnancy at various stages. Biopsy of the first and second polar body has the advantage of avoiding cell removal from the developing embryo. However, two separate micromanipulation procedures are required, and genetic abnormalities of paternal origin are not detected. Biopsy of cleavage-stage embryos (6- to 8-cell stage) allows evaluation of both maternal and paternal contribution to the genome (Fig. 21-14). However, biopsy at this stage may only partially reflect the embryo's genetic makeup if mitotic nondisjunction has occurred and embryonic mosaicism has been created. In addition, biopsied normal embryos may have a slightly lower implantation rate. Instead, biopsy of the trophectoderm at the blastocyst stage can offer several advantages (see Fig. 21-14B). The trophectoderm is the layer from which trophoblasts and thus the placenta develop. Biopsy from this layer allows evaluation of several cells but avoids removal of inner cell mass (fetal) cells. However, biopsy of embryos at this late stage generally requires embryo cryopreservation. Genetic analysis and reporting cannot be performed fast enough to allow embryo transfer in the same cycle.

Once cells are extracted, they are tested for structural aberrations and/or aneuploidy. Common testing options include single-nucleotide polymorphism (SNP) plus comparative genomic hybridization (CGH) microarrays or quantitative polymerase chain reaction. To analyze single cells for disease-specific DNA mutations, linkage analysis and DNA sequencing are generally used. Most recently, next-generation sequencing (NGS) has been used for all aspects of PGT. NGS has been rapidly adopted because of its potential to enhance efficiency and precision and lower costs (American Society for Reproductive Medicine, 2018).

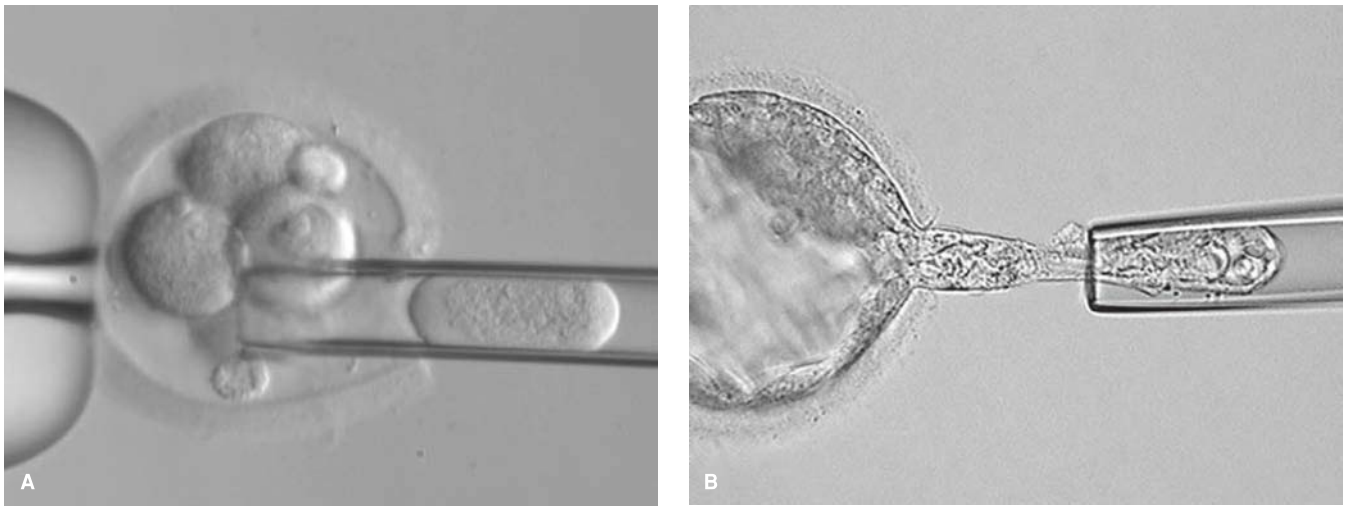

FIGURE 21-14 A. Photomicrograph of embryo biopsy. **B.** Photomicrograph of trophectoderm biopsy.

More recently, noninvasive PGT uses *spent embryo media (SEM)* to amplify cell-free DNA (cfDNA) to infer the embryo's karyotype. Of advantages, SEM collection requires no specialized training, and embryo disruption is negligible. Regarding SEM accuracy, comparisons between SEM cfDNA and "whole blastocyst" or trophectoderm biopsy show ploidy concordance rates that range from 30 to 87.5 percent (Belandres, 2019). Noninvasive PGT is unlikely to be adopted until at least 95 percent concordance rates can be achieved. This will require improvements in whole genome amplification (WGA) techniques.

Complications of Assisted Reproductive Technology

In most cases, ART leads to successful delivery of healthy singleton pregnancies. However, some pregnancy complications may develop more frequently in those conceived using ART. Of maternal risks, preeclampsia, placenta previa, and placental abruption are more common in IVF-conceived pregnancies (Table 21-6). Whether these greater risks are attributable to ART or to patient factors is unclear. One recent study found that risks for severe maternal morbidity were higher for women with conceptions achieved through infertility treatment (Luke, 2019). Specifically, in those conceived by IVF, risks were greater with pregnancy not conceived from autologous fresh cycles.

For the fetus, multifetal gestation is the most common risk. For singleton gestations, IVF has been associated with perinatal mortality, preterm delivery, low birthweight, and fetal-growth restriction. These trends persist even following adjustment for age and parity (Reddy, 2007). Other studies, however, have not confirmed this increased risk for singletons (Fujii, 2010). Additionally, congenital anomalies and epigenetic issues are concerns (see Table 21-6).

Discussions regarding the risks for congenital anomalies began shortly after the initial success of IVF and intensified following the use of ICSI. Specifically, studies do suggest a higher incidence of congenital anomalies in neonates conceived with ovulation induction, IUI, or IVF compared with those from the general population (El-Chaar, 2009; Reddy, 2007). Interpretation of most published studies, however, is complex. For example, the patient population undergoing IVF differs from the general obstetric population with respect to age and other factors. If data are adjusted for maternal age or duration of subfertility, the risk of congenital anomalies does not appear to be increased with ART (Shevell, 2005; Zhu, 2006). This implies that much of the risk is intrinsic to the infertile couple and not related to the procedure itself. Certain rare childhood cancers, such as embryonal hepatic tumors, are more common in IVF-conceived offspring. However, the risk more likely is attributable to underlying patient factors than to the IVF process (Spector, 2019).

An increase in the risk of epigenetic issues also has been reported. Although these conditions appear to be rare, their

TABLE 21-6. Potential Risks in Singleton IVF Pregnancies

	Absolute Risk (%)	RR (95% CI)[a]
Neonatal Complications		
Preterm birth	10.3	1.70 (1.60-1.81)
Low birthweight (<2500 g)	7.7	1.65 (1.53–1.78)
Small for gestational age	7.8	1.04 (0.97–1.12)
NICU admission	7.9	1.07 (1.02–1.12)
Neonatal mortality	0.28	1.67 (1.09–2.56)
Major birth defect	2.1	1.25 (1.09–1.44)
Maternal Complications		
Pregnancy hypertension	12.6	1.22 (1.15–1.28)
Placental complications	5.2	2.81 (2.57–3.08)
Gestational diabetes	8.2	1.41 (0.85–2.34)
Prenatal hospitalization	5.3	1.81 (1.65–1.97)
Primary cesarean delivery	32.2	1.20 (1.17–1.24)

[a]Compared with pregnancies not conceived by in vitro fertilization (IVF).
CI = confidence interval; NICU = neonatal intensive care unit; RR = relative risk.
Data from Luke, 2017a,b; 2019a,b.

importance cannot be overstated. For review, each autosomal gene is represented by two copies, or alleles, and one copy is inherited from each parent. For most genes, both alleles are expressed simultaneously. However, approximately 150 human genes are *imprinted*, and with these genes, only one of the alleles is expressed. Imprinted genes are under control of an imprinting center that directs embryogenesis and viability. Alteration of the cellular environment can interfere with this regulation and may follow gamete manipulation or inadequate in vitro culture conditions. As a result, accelerated embryo growth, birth complications, placental abnormalities, and polyhydramnios have been observed in nonhuman mammalian ART pregnancies. In humans, imprinted genes may contribute to behavior and language development, alcohol dependency, schizophrenia, and bipolar affective disorders. Imprinting may also raise risks for obesity, cardiovascular disease, and cancers. Of imprinting disorders, only rates of the rare Beckwith-Wiedemann syndrome are currently suggested to be higher in human ART. Causation has not been conclusively proven. However, in view of the above increased risks, more intensive prenatal assessment in pregnancies conceived by IVF is reasonable.

Last, studies assessing cognitive development after ART are reassuring for the most part. Many studies are suboptimal due to small sample size, choice of comparison group, and confounding and mediating factors (Carson, 2010). Fortunately, currently available data suggest that the psychomotor development of preschool children conceived by IVF does not differ from that of naturally conceived children. Similarly, the socioemotional development of children conceived by IVF appears comparable with that of naturally conceived children (Ludwig, 2006).

CONCLUSION

Treatment of infertility is typically initiated only after a thorough investigation (Chap. 20, p. 434). In general, identified contributors to subfertility are addressed first. However, in many cases, no obvious cause is found. In others, the cause(s) may be discovered but not amenable to directed corrective therapies. In these circumstances, generalized fertility-boosting strategies may be recommended. These include IUI (with or without superovulation) and ART. Importantly, superovulation and ART are not without risks, and couples should be appropriately counseled. Additionally, these techniques may involve donors or gestational carriers and are associated with unique psychosocial, legal, and ethical considerations. Emerging technologies such as PGT and uterus transplantation bring additional ethical issues to be addressed and resolved.

MENOPAUSAL TRANSITION

Menopausal transition is a progressive endocrinologic decline in hormone levels that takes a reproductive-aged woman from regular, cyclic menses to her final menstrual period, ovarian senescence, and beyond. With medical advancements, average life expectancy has risen, and most healthy women can now expect to live at least one third of their lives in the menopause. Life expectancy for women in 2014 approximated 81 years (Arias, 2019). Specifically, by 2050, approximately 47 million women will be aged 45 to 64 years (U.S. Census Bureau, 2017). Importantly, menopausal transition and years spent in the postmenopausal state bring with them issues related to quality of life and disease prevention and management.

DEFINITIONS

Menopause refers to a point in time that follows 1 year after the complete cessation of menstruation, and the *postmenopause* describes years following that point. The average age of women experiencing their final menstrual period (FMP) is 51.5 years, but a halt to menses from ovarian failure may occur at any age. Cessation before age 40, termed *premature ovarian insufficiency*, is associated with elevated follicle-stimulating hormone (FSH) levels, and its variable causes are described in Chapter 17 (p. 375). *Menopausal transition (MT)*, often referred to as *perimenopause* or *climacteric*, refers to the late reproductive years, usually late 40s to early 50s (Harlow, 2012; Santoro, 2005). Characteristically, MT begins with menstrual cycle irregularity and extends to 1 year after permanent cessation of menses. This reproductive aging with loss of follicular activity progresses within a wide age range (42 to 58 years). The average age at its onset is 47 years, and MT length was found in the multiethnic Study of Women Across the Nation (SWAN) to range from 4 to 8 years. MT lasted longer in women who had earlier transition onset and in those who smoked (Paramsothy, 2017).

As chronologic age is an unreliable indicator, classification of reproductive aging has been proposed. The first was developed in 2001 and updated in 2012 at the Stages of Reproductive Aging Workshop +10 (STRAW) (Harlow, 2012). These staging criteria are guides rather than strictly applied diagnoses. For example, every stage may not manifest in all women, or a stage may present out of the expected sequence. Moreover, the age range and duration of each stage varies among individuals.

In the STRAW system, the anchor stage is the FMP (Fig. 22-1). Five stages precede and two stages follow the FMP. Stage +1a is the first year after FMP, stage +1b reflects years 2 to 5 postmenopause, and stage +2 refers to the ensuing later postmenopausal years, in which estrogen levels continue to decline.

INFLUENTIAL FACTORS

Environmental, genetic, and surgical influences may alter ovarian aging. Smoking advances the age of menopause by approximately 2 years (Gold, 2001; Paramsothy, 2017). Chemotherapy, pelvic radiation, hysterectomy, ovarian surgery, and autoimmune disease also may lead to earlier menopause.

During MT, more erratic fluctuations in female reproductive hormone levels lead to physical and psychological symptoms (Table 22-1) (Dennerstein, 1993; Santoro, 2016a). Diet, exercise, reproductive history, socioeconomic status, body mass index (BMI), mood, climate, and individual or cultural attitudes toward menopause may explain symptom variation (O'Neil, 2011).

							FMP				
Stage	–5	–4	–3b	–3a	–2	–1		+1a	+1b	+1c	+2
	Early	Peak	Late		Early	Late		Early			Late
Terms	**Reproductive**				**Menopause transition**			**Postmenopause**

PHYSIOLOGIC CHANGES

Ovary

Physiologic changes seen during MT stem from atresia of the existing pool of ovarian follicles and cessation of reproductive hormone production. Ovarian senescence is a process that begins in utero within the embryonic ovary due to programmed oocyte atresia (Fig. 15-1, p. 321). From birth onward, primordial follicles continuously are activated, mature partially, and then regress. This follicular activation continues in a constant pattern that is independent of pituitary stimulation.

A more rapid depletion of ovarian follicles starts in the late 30s and early 40s and continues until a point at which the menopausal ovary is virtually devoid of follicles (Figs. 22-2 and 22-3). The process of atresia of the nondominant cohort of follicles, largely independent of menstrual cyclicity, is the prime event that leads to the eventual loss of ovarian activity and menopause. In one study, investigators performed a quantitative histologic study of the endometrium and ovaries of women aged 44 to 55 years in MT undergoing hysterectomy for benign indications (Richardson, 1987). The women who reported regular cycles had an average of 1700 follicles in a selected ovary, but those with irregular cycles had an average of 180.

TABLE 22-1. Symptoms Associated with Menopausal Transition

Menstrual pattern	**Sexual dysfunction**
Shorter cycles (typical)	Vaginal dryness
Longer cycles (possible)	Decreased libido
Irregular bleeding	Dyspareunia
Vasomotor	**Somatic**
Hot flashes	Headache
Night sweats	Dizziness
Sleep disturbances	Palpitations
Psychological/cognitive	Joint aches and back pain
Worsening PMS	**Others**
Depression	Urinary incontinence
Irritability	Dry, itchy skin
Mood swings	Weight gain
Poor concentration	
Poor memory	

PMS = premenstrual syndrome.

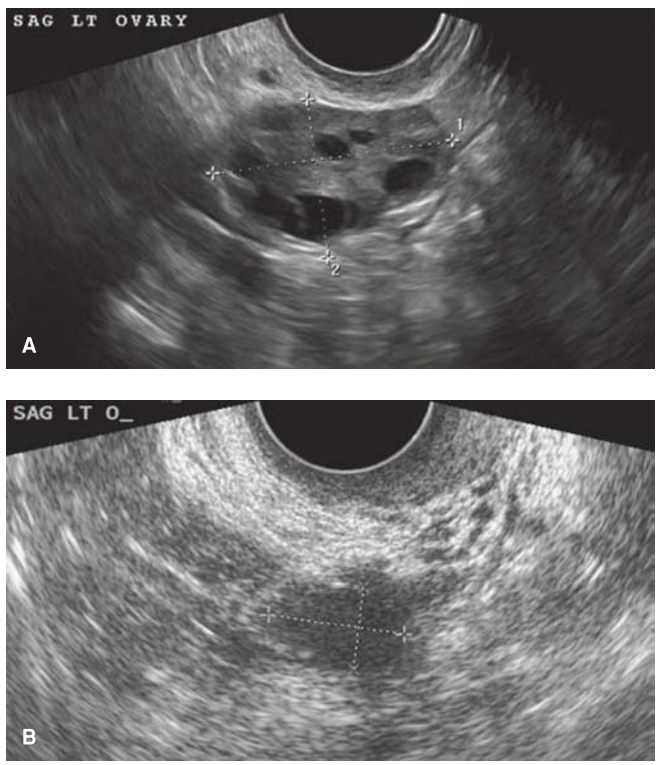

FIGURE 22-2 Transvaginal sonographic images of a pre- and postmenopausal ovary. **A.** In general, premenopausal ovaries have greater volume and contain follicles, which are seen as multiple, small, anechoic, smooth-walled cysts. **B.** In comparison, postmenopausal ovaries have smaller volume and are characteristically devoid of follicular structures. (Reproduced with permission from Dr. Elysia Moschos.)

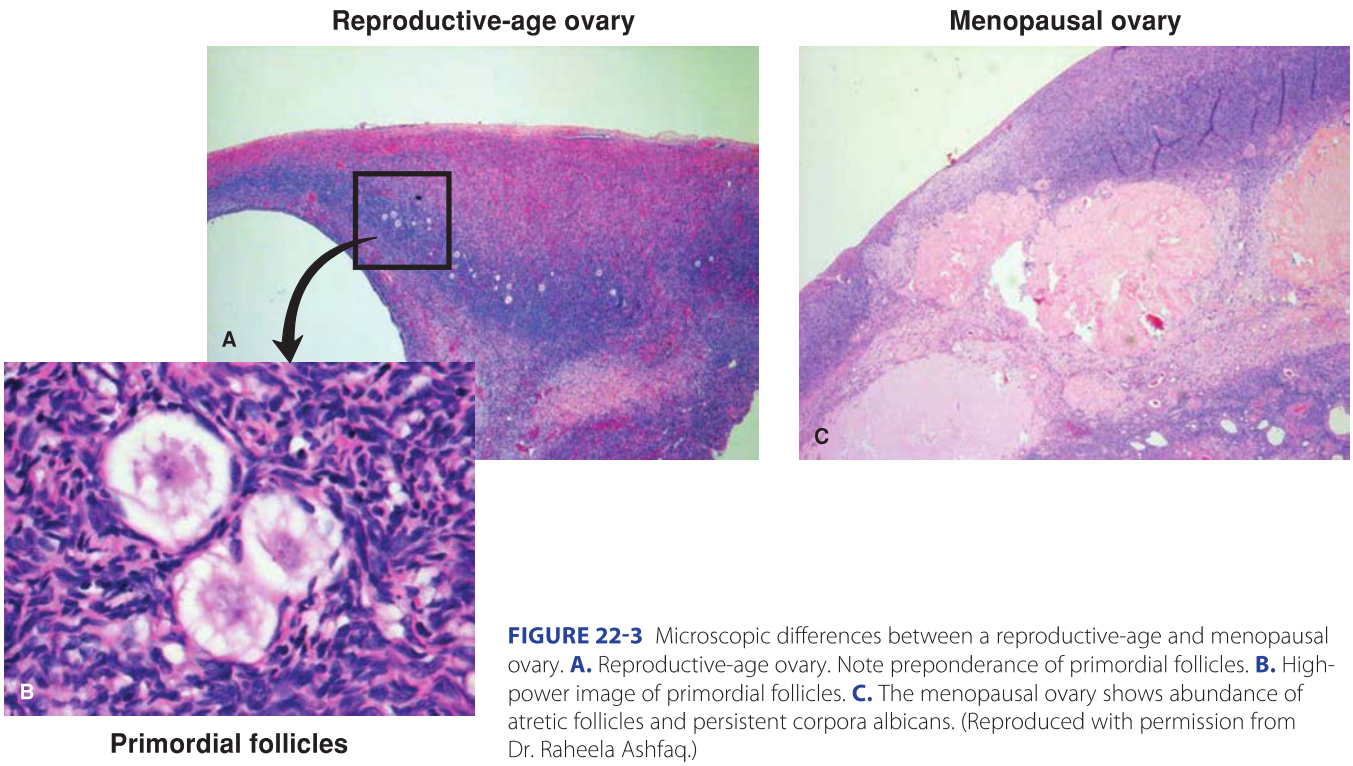

FIGURE 22-3 Microscopic differences between a reproductive-age and menopausal ovary. **A.** Reproductive-age ovary. Note preponderance of primordial follicles. **B.** High-power image of primordial follicles. **C.** The menopausal ovary shows abundance of atretic follicles and persistent corpora albicans. (Reproduced with permission from Dr. Raheela Ashfaq.)

Ovarian Reserve

During MT, the dwindling follicle pool is reflected by low inhibin B and antimüllerian hormone (AMH) levels and by low antral follicle counts measured sonographically. However, none of these measures are recognized tools to diagnose menopause. Instead, AMH is most appropriately used to evaluate ovarian reserve in women with infertility (American College of Obstetricians and Gynecologists, 2019b).

AMH is a glycoprotein secreted by the granulosa cells of secondary and preantral follicles and indirectly reflects the primordial follicle pool. Circulating AMH concentrations are highly reproducible as they remain relatively stable across the menstrual cycle in reproductive-aged women and correlate with the number of early antral follicles. AMH levels decrease markedly and progressively across MT (Hale, 2007; Kushnir, 2017). Levels are often very low, or even below detectable limits, approximately 5 years before menopause (Bertone-Johnson, 2018; Broer, 2014).

Hypothalamic-Pituitary-Ovarian Axis

The failing pool of ovarian follicles leads to characteristic changes in the hypothalamic–pituitary–ovarian axis. To review, during the reproductive years, gonadotropin-releasing hormone (GnRH) is released in a pulsatile fashion by the arcuate nucleus of the medial basal hypothalamus. It binds to GnRH receptors on the pituitary gonadotropes to stimulate cyclic luteinizing hormone (LH) and FSH release. These gonadotropins, in turn, stimulate ovarian production of estrogen, progesterone, and inhibin. Estrogen and progesterone exert positive and negative feedback on pituitary gonadotropin production and on the amplitude and frequency of GnRH release. Produced by granulosa cells, inhibin also exerts an important negative influence on FSH secretion from the pituitary. This tightly regulated endocrine system leads to regular, ovulatory menstrual cycles.

In early MT (stage –2), usually beginning in the late 40s, FSH levels rise slightly to stimulate an enhanced ovarian follicular response, which raises overall estrogen levels (Jain, 2005; Klein, 1996). This FSH rise is attributed to decreased ovarian inhibin secretion rather than diminished estradiol (E_2) feedback. In perimenopausal women, E_2 production fluctuates with FSH levels and can reach concentrations even higher than those observed in women younger than 35. Generally, E_2 levels do not drop significantly until late in MT. Despite ongoing regular cyclic menstruation, progesterone levels during the early MT are lower than in mid-reproductive-aged women (Santoro, 2016a). Testosterone levels do not vary appreciably during the MT. However, sex hormone–binding globulin (SHBG) production declines after the menopause and may lead to relatively higher levels of free or unbound estrogen and testosterone.

In late MT, women exhibit impaired folliculogenesis and greater rates of anovulation compared with women in their mid-reproductive years. Also, during this time, ovarian follicles undergo an accelerated rate of loss until eventually, in late MT, the supply of follicles is depleted. These changes, including the earlier-described rise in FSH levels, reflect the reduced capability of aging follicles to secrete inhibin (Reyes, 1977; Santoro, 1996).

In stage +1a, the first year after the FMP, ovarian progesterone production ceases. Estrogen levels fluctuate and gradually decline. With ovarian failure in the menopause (stage +1b), ovarian steroid hormone release ceases, and the negative-feedback loop is opened. As a result, GnRH is released at maximal frequency and amplitude. In turn, circulating FSH and LH levels rise up to fourfold higher than those in the reproductive years (Klein, 1996).

In stage +2, which reflects the ensuing later postmenopausal years, estrogen is made primarily from conversion of androgens within adipose tissue.

Endometrium

Histologic changes in the endometrium directly represent systemic estrogen and progesterone levels and thus may change dramatically depending on the MT stage. During early MT, the endometrium may reflect ovulatory cycles, which are prevalent during this time. During later MT stages, anovulation is common, and the endometrium will display an estrogenic effect that is unopposed by progesterone. Accordingly, proliferative changes or disordered proliferative changes are frequent findings on pathologic examination of endometrial biopsy samples. After menopause, the endometrium becomes atrophic due to lack of estrogen stimulation (Fig. 16-19, p. 358).

Menstrual Disturbances

The physiologic changes described in the prior sections lead to menstrual variation and finally amenorrhea (see Fig. 22-1). In the early MT (stage –2), a woman's menstrual cycles remain regular, but the interval between cycles may be altered by ≥7 days or the woman may note that expected menses are skipped. Typically, cycle lengths become shorter.

The late MT (stage –1) is characterized by two or more skipped menses and at least one intermenstrual interval ≥60 days due to progressively higher rates of anovulation. Circulating estrogen levels are likely to be low during anovulatory cycles. The most profound hormonal changes occur during this time, and symptomatology intensifies when amenorrhea duration is prolonged (Santoro, 2016a).

Many women in their mid to late 40s do not consider themselves fertile and will cease contraception but will still have occasional ovulatory cycles. Contraception can be discontinued by all women at age 55. Some women older than 55 years may still have menstrual bleeding. However, ovulation is rare and oocytes are likely poor quality and rarely viable (Gebbie, 2010).

During MT, abnormal uterine bleeding (AUB) is common, and Treloar (1981) found that menses were irregular in more than one half of all women studied. Paramsothy (2014) reported that AUB accounted for 14 percent of all hospitalizations from 1998 to 2005 among women aged 45 to 54. Anovulation is the most common cause of erratic bleeding during MT. However, because the time interval surrounding menopause is characterized by relatively high, acyclic estrogen levels and relatively low progesterone production, women in MT are at higher risk for developing endometrial hyperplasia or carcinoma. Symptoms associated with estrogen-sensitive pathology, including endometrial polyps, uterine leiomyomas, and adenomyosis, also become more prevalent.

In all women, regardless of menopausal status, the etiology of AUB should be determined as outlined in Chapter 8 (p. 182). As noted, endometrial cancer is suspected in any woman in MT with AUB. The overall incidence of endometrial cancer approximates 0.1 percent of women in this group per year. In women with AUB in MT, however, the risk rises to 10 percent (Lidor, 1986). Thus, endometrial biopsy is done to exclude neoplasia.

Although endometrial cancer is the greatest concern during this time, endometrial biopsy frequently reveals a benign endometrium that displays estrogen effects unopposed by progesterone. In premenopausal women, this results from anovulation. In postmenopausal women, unopposed estrogen typically originates from extragonadal endogenous estrogen production. This derives from increased conversion of adrenal androgens to estrogen by the enzyme aromatase found in adipose tissue. In addition, lower SHBG levels lead to higher levels of free and therefore bioavailable estrogen (Moen, 2004). Less often, unopposed exogenous estrogen administration or an estrogen-producing ovarian tumor also can account for these effects in postmenopausal women.

Adrenal Steroid Levels

With advancing age, adrenal production of dehydroepiandrosterone sulfate (DHEAS) declines. In women aged 20 to 30 years, DHEAS concentrations peak at an average level of 6.2 μmol/L, and then decrease steadily. In women aged 70 to 80 years, DHEAS levels are diminished by 74 percent to a level of 1.6 μmol/L. Other adrenal hormone levels similarly fall with aging (Burger, 2000; Labrie, 1997). Androstenedione and pregnenolone show comparable declines. The ovary contributes to the production of these hormones during the reproductive years, but after menopause, only the adrenal gland continues this hormone synthesis.

Burger and associates (2000) prospectively studied 172 women during MT as a part of the Melbourne Women's Midlife Health Project. Analyzing hormone levels longitudinally in these women, they observed no relationship between a woman's FMP and the decline in DHEAS levels. Advancing age, regardless of menopausal status, determined DHEAS level decline.

Central Thermoregulation

Of the many menopausal symptoms that may affect quality of life, the most frequent are those related to thermoregulation dysfunction. Kronenberg (1990) tabulated all of the published epidemiologic studies and determined that *vasomotor symptoms (VMS)*, also variably termed *hot flashes*, *hot flushes*, and *night sweats*, developed in 11 to 60 percent of menstruating women during MT. In the Massachusetts Women's Health Study, the incidence rose from 10 percent during the premenopausal period to approximately 50 percent after menses cessation (McKinlay, 1992).

Hot flashes begin an average of 2 years before the FMP, and 85 percent of women who experience them will continue to experience them for more than 1 year. Of these women, 25 to 50 percent will have hot flashes for 5 years, and >15 percent may experience them for >15 years (Kronenberg, 1990). More recent studies focusing on duration of menopausal symptoms indicate that women can expect hot flashes to continue, on average, for 7 years. Black women experience the longest duration (10 years), compared with Hispanic (9 years), white (7 years), and Asian women (5 years) (Avis, 2015).

Four trajectories of hot flash onset and duration were identified in the SWAN study: early onset, late onset, low frequency, and high frequency. Those with an early, high-frequency pattern had an onset that began before the FMP and continued up to 14 years, which was the observation period length (Tepper, 2016).

Vasomotor Symptoms

Thermoregulatory and cardiovascular changes that accompany a hot flash are well documented. An individual hot flash generally lasts 1 to 5 minutes, and skin temperatures rise because of peripheral vasodilation (Kronenberg, 1990). This change is particularly marked in the fingers and toes, where skin temperature can rise 10 to 15°C. Most women sense a sudden wave of heat that spreads over the body, particularly the upper body and face. Sweating begins primarily on the upper body, and it corresponds closely in time with an increase in skin conductance (Fig. 22-4). Sweating has been observed in women during 90 percent of hot flashes (Freedman, 2001).

Elevations in both awake and sleep systolic blood pressure are noted with hot flashes (Gerber, 2007). Heart rate rises 7 to 15 beats per minute at approximately the same time as peripheral vasodilation and sweating. Heart rate and skin blood flow usually peak within 3 minutes of the hot flash onset. Simultaneously with sweating and peripheral vasodilation, the metabolic rate also significantly rises. Hot flashes can also be accompanied by palpitations, anxiety, irritability, and panic.

Starting 5 to 9 minutes after a hot flash begins, the core temperature declines 0.1 to 0.9°C due to increased peripheral vasodilation (Molnar, 1981). If heat loss and sweating are significant, a woman may experience chills. Skin temperature gradually returns to normal, sometimes taking 30 minutes or longer.

Vasomotor Symptom Pathophysiology

Although the underlying physiologic steps leading to hot flashes are not fully elucidated, dysfunction of the thermoregulatory nucleus of the hypothalamus appears relevant. This nucleus regulates perspiration and vasodilation to manage heat loss in humans. If exposed to higher temperatures, the nucleus activates these heat dissipation mechanisms. This maintains core body temperature in a regulated normal range, called the *thermoregulatory zone*. Women who experience more severe VMS are thought to have a narrower thermoregulatory zone than those without symptoms. In these women, minimal changes in core body temperature induce shivering or hot flash.

Various hormones and neurotransmitters modulate hot flash frequency. Of these, estrogens play a vital role. Although not clearly correlated, estrogen withdrawal or rapid level fluctuation rather than a chronically low estrogen concentration are associated with symptoms (Erlik, 1982; Overlie, 2002). This hypothesis is supported by the fact that women with gonadal dysgenesis (Turner syndrome), who lack normal estrogen levels, do not experience hot flashes unless first exposed to estrogen and then withdrawn from treatment.

In addition, altered neurotransmitter concentrations are believed to create a narrow thermoregulatory zone and to lower the sweating threshold (Freedman, 1998, 2014). Norepinephrine is thought to be the primary neurotransmitter responsible for lowering the thermoregulatory setpoint and triggering the heat loss mechanisms associated with hot flashes (Rapkin, 2007). Plasma levels of norepinephrine metabolites rise before and during hot flashes. Moreover, norepinephrine injections can elevate core body temperature and induce a heat loss response (Freedman, 1990). Medications that decrease norepinephrine levels, such as clonidine, may reduce VMS (Laufer, 1982).

Estrogens are known to modulate adrenergic receptors in many tissues. Freedman and colleagues (2001) suggested that menopause-related declines in estrogen levels lower hypothalamic α_2-adrenergic receptor concentrations. In turn, a decline

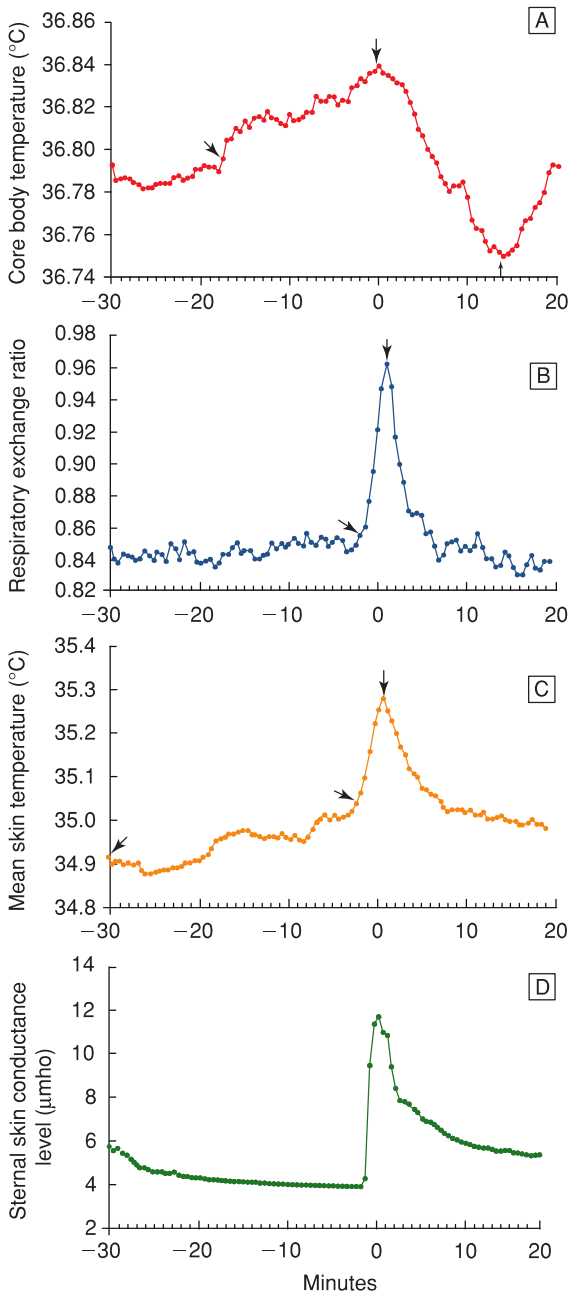

FIGURE 22-4 Physiologic changes (means) during a hot flash. **A.** Core body temperature. **B.** Respiratory exchange ratio. **C.** Skin temperature. **D.** Sternal skin conductance. Time 0 is the beginning of the sternal skin conductance response. (Reproduced with permission from Freedman RR: Biochemical, metabolic, and vascular mechanisms in menopausal hot flashes. Fertil Steril 70(2):332, 1998.)

in presynaptic α_2-adrenergic receptor levels leads to higher norepinephrine levels, thereby causing VMS.

Serotonin appears to represent another neurotransmitter involved in VMS (Slopien, 2003). Estrogen withdrawal is associated with a decreased blood serotonin level, which is followed by upregulation of serotonin receptors in the hypothalamus. Activation of specific serotonin receptors mediates heat loss (Gonzales, 1993). However, the role of serotonin in central regulatory pathways is complex because binding at some serotonin receptors can exert negative feedback on other serotonin receptor types (Bachmann, 2005). Therefore, the effect of a change in serotonin activity depends on the type of receptor activated.

Of other potential candidates, β-endorphins and other neurotransmitters affect the thermoregulatory center and make some women more prone to hot flashes (Pinkerton, 2009a). Newer studies implicate the KNDy (kisspeptin/neurokinin B/dynorphin) neuron class in the hypothalamic arcuate nucleus. KNDy neurons contain estrogen receptors and act in response to E_2 (Rance, 2013). One randomized trial of healthy women found that neurokinin B infusion induced hot flashes (Jayasena, 2015). Moreover, neurokinin B–receptor antagonists reduced self-reported hot flash rates by 45 percent during a 3-month trial (Prague, 2017).

Genetic polymorphisms and VMS prevalence and severity also may be linked. Some polymorphisms are variants of genes encoding estrogen receptor α (Crandall, 2006; Malacara, 2004). Others are single-nucleotide polymorphisms (SNPs) involved in E_2 synthesis or metabolism or in its conversion to more- or less-potent estrogens. More recently, SNPs in regions of the *tachykinin receptor 3* gene, which codes for the neurokinin B receptor (NK3R), were associated with menopausal VMS (Crandall, 2017). Another implicated neurotransmitter is *calcitonin gene–related peptide*, which raises skin temperatures in ovariectomized rats (Hay, 2009).

In sum, studies suggest that reductions and fluctuations in estrogen levels lead to a decline in inhibitory presynaptic α_2-adrenergic receptor concentrations and an increase in hypothalamic norepinephrine and serotonin release. Norepinephrine and serotonin lower the setpoint in the thermoregulatory nucleus and allow heat loss mechanisms to be triggered by subtle changes in core body temperature. The KNDy signal system also may play a role, which may lead to new nonhormonal treatment options.

Vasomotor Symptom Risk Factors

Several risk factors are associated with hot flashes. These are early or surgical menopause, race or ethnicity, BMI, sedentary lifestyle, smoking, and use of selective estrogen-receptor modulators or aromatase inhibitors. Others include premenstrual dysphoric disorder, anxiety, perceived stress, and depression (Avis, 2015; Gold, 2006; Guthrie, 2005). Moreover, women exposed to high ambient temperatures may experience more frequent and severe hot flashes (Randolph, 2005).

Among these factors, surgical menopause is associated with a 90-percent probability of hot flashes during the first year after oophorectomy. Symptoms can be more abrupt and severe than those associated with natural menopause. Both hysterectomy and unilateral oophorectomy are associated with an earlier menopause.

Among racial and ethnic groups, hot flashes appear to be more common and more bothersome in African-American than in white women and are more common among white than among Asian women (Avis, 2015; Gold, 2001; Thurston, 2008). These racial/ethnic differences in VMS persisted even after controlling for other influencing factors (Al-Safi, 2014).

The effect of BMI on hot flash frequency is unclear. Some studies find hot flashes associated with both obesity and sedentary lifestyle (Da Fonseca, 2013; Hunter, 2012; Saccomani, 2017; Wilbur, 1998).

Hot flashes and trouble sleeping may reflect posttraumatic stress disorder (PTSD) from past or ongoing intimate partner violence (IPV) or sexual assault. An observational study of 2016 healthy women assessed lifetime IPV and sexual assault rates and their effects using standardized questionnaires (Gibson, 2019). Reported rates of PTSD symptoms, emotional abuse, physical violence, and sexual assault ranged from 16 to 22 percent. Of affected women, difficulty sleeping was reported by approximately 52 percent; hot flashes, by 40 percent; and night sweats, by 34 percent. Sexual problems also were common. Rates of vaginal dryness approximated 30 percent, and painful intercourse or vaginal irritation each was noted in about 15 percent.

PATIENT EVALUATION

During MT, clinical goals aim to optimize a woman's health and well-being during and after this transition. This is an excellent time for a comprehensive health evaluation, as outlined in Chapter 1 (p. 9).

During patient visits, changes affected by aging and MT are documented. Height, weight, waist circumference, and BMI are recorded and can be used to counsel women about physical exercise and weight loss or weight gain. Height loss may be associated with osteoporosis and vertebral compression fractures and thus is recorded yearly. The remaining examination notes expected physiologic changes of MT and identify potential pathology.

The diagnosis of MT can usually be made with age-appropriate symptoms and careful physical examination. Clearly, a 50-year-old woman with menstrual irregularity, hot flashes, and vaginal dryness is considered to be in MT. Other specific genitourinary physical findings are described later (p. 495).

Measurement of serum FSH or E_2 levels, described next, can be performed to document ovarian failure. However, for those in MT, FSH levels may be normal. Even for much younger women with similar symptoms, evaluation should also include FSH level measurement. In addition, pregnancy should be excluded if applicable. If ovarian failure develops before age 40, it is usually pathologic. Thus, chromosomal abnormalities, infections, autoimmune disorders, galactosemia, cigarette smoking, or iatrogenic causes such as radiation or chemotherapy are considered (Table 17-7, p. 384).

Gonadotropin and Estrogen Levels

Biochemical changes, of which a woman may be unaware, may be identified prior to cycle irregularity. For example, in the early follicular phase of the menstrual cycle in many women

older than 35 years, FSH levels may rise without a concurrent LH elevation. This finding is associated with a poor prognosis for future fertility. Specifically, a cycle-day-3 FSH level greater than 10 mIU/mL is used in some in vitro fertilization programs to route patients into donor egg programs (Chap. 21, p. 459). An FSH level greater than 40 mIU/mL is used to document ovarian failure associated with menopause.

Estrogen levels may be normal, elevated, or low depending on the stage of MT. Only at menopause are serum E_2 levels extremely low or undetectable. As another use, E_2 levels may assess a woman's response to hormone treatment. Most clinicians prefer to reach a physiologic serum E_2 range of 50 to 100 pg/mL when adjusting treatment. Women who receive E_2 pellets may have elevated serum values from 300 to 500 pg/mL. Because these high levels are not uncommon with this approach, pellet use for hormone therapy is discouraged.

THE MATURE WOMAN

With ovarian senescence, declining hormone levels have specific effects. Some lead to physical symptoms, such as VMS and vaginal dryness. Metabolic and structural changes include bone loss, skin thinning, fatty replacement of the breast, lipoprotein changes, and genitourinary atrophy. As a result, postmenopausal women have unique issues associated with aging and estrogen loss that may negatively affect their individual health.

Estrogen, progestogen (a term that encompasses synthetic progestins and progesterone), and androgen therapy have been used by menopausal women for more than 100 years. Recent history surrounding menopausal hormone therapy is discussed here, as are current recommendations for symptom treatment.

HORMONE TREATMENT: HISTORY AND CONTROVERSIES

Hormone therapy (HT) has been extensively studied and evidence-based recommendations continue to evolve. The 2017 Position Statement regarding HT published by The North American Menopause Society (2017) can serve as a valuable resource. In the following discussion, HT serves as an umbrella term that encompasses both estrogen-only therapy (ET) and estrogen-progesterone therapy (EPT).

Evolution of Knowledge

ET for menopausal symptom relief gained popularity in the 1960s and 1970s. Proponents cited its effects to "preserve youth" and prevent chronic disease. By the mid-1970s, oral ET use was prevalent among US women. However, also in the mid-1970s, epidemiologic studies revealed that ET use among menopausal women with an intact uterus was associated with a substantially elevated risk of endometrial cancer (Smith, 1975). As a result, the U.S. Food and Drug Administration (FDA) package labeling for menopausal ET changed to reflect this risk. By the 1980s, clinicians began to prescribe progestogens concurrently with ET for menopausal women with an intact uterus.

In the late 1980s, observational study results suggested that HT prevented osteoporosis, coronary heart disease (CHD), and dementia in menopausal women. Positive findings of these observational studies, including the large Nurses' Health Study (NHS), initially appeared discordant with those of subsequent randomized clinical trials of HT, specifically the Women's Health Initiative (WHI). However, these differences appear to derive from the mean age of HT initiation in these trials. For example, in the NHS, most participants were younger than 55 years and were within 2 to 3 years of menopause onset at the time they initiated HT. In contrast, the mean age of WHI participants at recruitment was 63 years, and most were more than 10 years beyond menopause onset. When NHS and WHI findings for participants who initiated HT at age 50 to 59 years or within 10 years of menopause onset were compared, most outcomes were similar (Bhupathiraju, 2017).

These observations support the "timing hypothesis," which postulates that estrogen has a differential effect on vascular tissue during the early and late stages of atherosclerosis progression. In younger women or those recently menopausal, estrogen appears to slow atherosclerosis progression. In contrast, if advanced atherosclerosis is present, as is common in older women, initiating HT may precipitate vascular occlusion and thrombosis.

The ELITE trial, which was designed specifically to test the timing hypothesis, found that oral E_2 slowed progression of atherosclerosis when initiated by women within 6 years of menopause but not when initiated by women 10 or more years postmenopause (Hodis, 2016; Sripasert, 2019). Evidence also suggests that early HT initiation may enhance insulin action and possibly aid Alzheimer disease prevention (Imtiaz, 2017; Pereira, 2015).

Women's Health Initiative

Launched in 1993, this study's goal was to evaluate the putative protective effects of HT on common chronic diseases of aging. The WHI compared the effects of a combined 0.625-mg conjugated equine estrogen (CEE)/2.5-mg medroxyprogesterone acetate (MPA) oral formulation with placebo in more than 16,000 healthy postmenopausal women aged 50 to 79 years with a uterus (EPT arm) (Rossouw, 2002). Specific end points evaluated included CHD, venous thromboembolism (VTE), breast and colon cancer, and bone fractures. Concurrently, the study also compared an oral 0.625-mg CEE dose alone against placebo in approximately 11,000 women without a uterus (ET arm).

WHI investigators selected CHD (anticipated benefit) and breast cancer (anticipated risk) as primary disease end points. After 5 years of monitoring, the EPT arm of the WHI was halted early upon recommendation of its Data and Safety Monitoring Board because overall risks exceeded benefits. In July 2002, results were released to the media. This preceded journal publication of the data and timely education of healthcare providers. As a result, widespread confusion and concern among women and clinicians followed.

In a subsequent detailed analysis of cardiovascular end points in the EPT arm, the hazard for cardiovascular death or nonfatal myocardial infarction with EPT was 1.24. This translated into 188 actual cases in the hormone group and 147

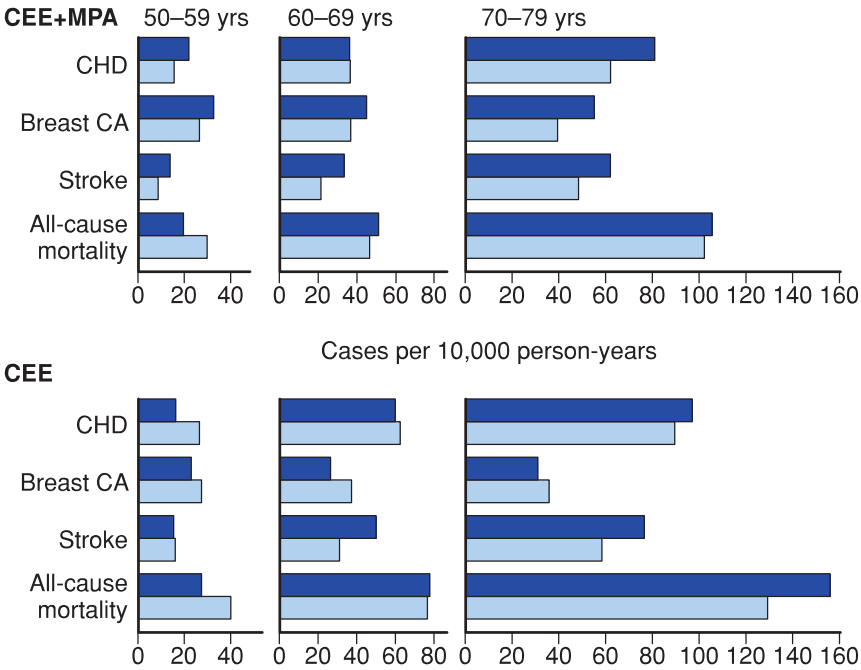

FIGURE 22-5 Graphs reflect the absolute risks of health outcomes in the Women's Health Initiative (WHI). Dark bars reflect outcomes of those administered hormones, whereas light bars reflect those women randomly assigned to placebo.

in the placebo group (Anderson, 2004). To explore the timing of HT initiation among WHI participants, Rossouw and colleagues (2007) looked specifically at HT's effect on stroke and CHD rates across categories of age and years since the menopause. Study women who initiated HT closer to menopause tended to have reduced CHD rates risk compared with a higher CHD risk seen among women more distant from menopause. Specifically, for the group aged 50 to 59 years in both study arms, the hazard ratio for CHD was 0.93, or two fewer events per 10,000 person-years. For the group aged 60 to 69 years, this ratio was 0.98 or 1 fewer event per 10,000 person-years, and for those 70 to 79 years, the ratio was 1.26 or 19 extra events per 10,000 person-years. HT increased the stroke risk—the hazard ratio was 1.32—and this risk did not vary significantly by age or time since menopause. These authors concluded, consistent with the timing hypothesis, that women who initiated HT closer to menopause tended to have reduced CHD risk compared with the greater CHD risk among women more distant from menopause. Importantly, evidence is insufficient to suggest that either ET or EPT should be initiated or continued for primary or secondary CHD prevention (American College of Obstetricians and Gynecologists, 2018b; The North American Menopause Society, 2017). Although the primary conclusion from the 2007 Rossouw article was that HT reduced CHD if initiated closer to menopause, confusion surrounding WHI findings has led providers and women, including healthy recently menopausal women with bothersome VMS, to avoid HT use (Manson, 2016).

Subsequently, a 2013 WHI report comprehensively reviewed findings from both study arms. This included extended outcome data stratified by age. Although risks and benefits of HT were observed, absolute risks in general were small. After administration of study medication stopped, most risks and benefits were attenuated. However, a small elevated risk of breast cancer persisted over 13 years with EPT. In contrast, ET reduced the breast cancer risk (Manson, 2013). Based on these WHI data, the attributed risk of breast cancer with EPT is less than one additional case of breast cancer per 1000 users. The hazard ratio of 1.28 is slightly higher than that observed with one daily glass of wine, less than that with two daily glasses, and similar to risks associated with obesity and low physical activity (The North American Menopause Society, 2017). With respect to CHD, findings in the 2013 WHI report provide further support for the timing hypothesis (Fig. 22-5) (Manson, 2013).

In an 18-year reevaluation of WHI participants, cardiovascular, cancer, and all-cause mortality rates were essentially identical in the HT and placebo groups. Although breast cancer mortality at 18 years was elevated in the EPT group, this increase did not achieve statistical significance. A significant reduction in breast cancer mortality was noted in the ET group. Of note, a significant reduction in mortality from Alzheimer disease or dementia was also noted with HT use (Manson, 2017).

Risk of Venous Thromboembolism

In the WHI and other HT studies evaluating oral estrogen, VTE risk approximately doubles (Rossouw, 2002). No randomized trials comparing oral and transdermal estrogen are adequately powered to compare risk of VTE. However, observational and database studies have found no elevated VTE risk with transdermal HT (Canonico, 2016; Vinogradova, 2019). These risk differences likely reflect a lesser effect on coagulation parameters with a transdermal compared with an oral route (Canonico, 2014). Similarly, lower-dose transdermal E_2 (≤0.05 mg daily), in contrast with oral estrogen, does not appear to increase risk of stroke. Accordingly, the transdermal route of estrogen administration is particularly appropriate for obese women and others with cardiovascular risk factors (Shifren, 2019).

CURRENT APPROACHES TO HORMONE THERAPY

Benefits and Risks

In the shared decision-making conversation between provider and patient, treatment goals and HT risks and benefits are presented (Table 22-2). Evidence supports HT as the most effective therapy for treatment of VMS. It also effectively prevents bone loss and fractures and treats genitourinary symptoms (American College of Obstetricians Gynecologists, 2018c). As detailed earlier, when initiated soon after the onset of menopause, HT may lower CHD rates, enhance insulin's action, and prevent Alzheimer disease.

TABLE 22-2. Some Effects of Hormonal Classes Used Short Term (5-Years) for Menopausal Symptoms

Target	CEE/MPA	E_2P (TD)	CEE	E_2 (TD)	RLX	BZE/CEE	OSP

Benefits Potential harms Neutral effects

BZE/CEE = bazedoxifene/conjugated equine estrogen; CEE = conjugated equine estrogen; DVT = deep-vein thrombosis; E_2 = estradiol; MPA = medroxyprogesterone acetate; OSP = ospemifene; P = progesterone; RLX = raloxifene; TD = transdermal; VMS = vasomotor symptoms.

Of risks, menopausal HT raises CHD risk if initiated in women aged ≥60 years or in those who are ≥10 years postmenopause. Across ages, HT also elevates the risk of stroke, VTE, and cholecystitis. Among women younger than 60 and those within 10 years of menopause onset, stroke is rare, and the attributed risk is <0.5 additional cases per 1000 oral HT users annually (Manson, 2013).

The breast cancer risk is modestly elevated with EPT use longer than 4 or 5 years. Detailed earlier, the attributed breast cancer risk with EPT is <1 additional case per 1000 EPT users annually (Manson, 2013) (p. 480). Short-term EPT use is not associated with an elevated breast cancer risk. ET with conjugated estrogens did not elevate the breast cancer risk in the 7 years of the WHI ET-alone arm.

Other Decision-Making Considerations

Based on current package labeling, HT is indicated only for treatment of bothersome VMS and genitourinary symptoms, prevention of osteoporosis, and treatment of hypoestrogenism caused by hypogonadism, surgical menopause, or premature ovarian insufficiency. Contraindications to the use of menopausal HT are listed in Table 22-3.

The appropriate type, dose, administration route, and duration guide HT selection for a given woman to achieve treatment objectives and enhance safety. Periodic changes in a woman's health status and shared decision-making will guide individual use over time (The North American Menopause Society, 2017).

For women with a uterus, ET increases the risk of endometrial neoplasia. EPT taken daily and continuously is associated with risk of endometrial cancer lower than or comparable to that observed in HT non-users. However, EPT taken as sequential progestogen therapy (e.g., 10 to 14 days each month) is associated with a slightly elevated risk of endometrial neoplasia (Anderson, 2003; Jaakola, 2009). In our practices, most patients use EPT daily and continuously, although intermittent, monthly progestogen may have less breast cancer risk.

Duration of Systemic Hormone Therapy

The optimal duration varies among women and relates to VMS, quality of life, osteoporosis risk, and patient comorbidities and preferences. Both the North American Menopause Society (2017) and the American College of Obstetricians and Gynecologists (2018c) recommend against arbitrary age-based

TABLE 22-3. Warnings and Precautions with Systemic Estrogen Administration

Estrogen should not be used in women with any of the following conditions:

Undiagnosed abnormal genital bleeding
Known, suspected, or history of breast cancer
Known or suspected estrogen-dependent neoplasia
Active or prior venous thromboembolism
Active or prior stroke, myocardial infarction, or TIA
Known thrombophilia
Liver dysfunction or disease
Untreated hypertension
Known hypersensitivity to the ingredients of the estrogen preparation
Known or suspected pregnancy

Estrogen should be used with caution in women with the following conditions:

Dementia
Gallbladder disease
Hypertriglyceridemia
Prior cholestatic jaundice
Hypothyroidism
Fluid retention plus cardiac or renal dysfunction
Severe hypocalcemia
Prior endometriosis
Hypothyroidism
Elevated breast cancer risk
Hepatic hemangiomas

Data from Food and Drug Administration, 2005; Kaunitz, 2015.

discontinuation and suggest a tailored approach. Although few data guide extended HT use or the method of discontinuation, the following approach is based on our clinical experience.

After several years, a patient is encouraged to try a lower HT dose, with the understanding that she can resume the prior HT dose if symptoms recur. This strategy can continue until the patient is using a low HT dose. This may be oral CEE (0.3 or 0.45 mg) or E_2 (0.5 mg) or transdermal E_2 (0.014 to 0.025 mg). After remaining VMS free on low-dose therapy, stopping HT is appropriate for many patients. However, for those with an elevated risk for osteoporosis or poor sense of well-being off systemic HT, continuing HT is reasonable.

The North American Menopause Society (2017) indicates that prevention of dementia should not be considered an indication for use of HT but also points out that some observational studies have found that HT initiation by recently menopausal women is associated with a lower risk of dementia. Accordingly, some recently menopausal women without contraindications to HT use and who do not report bothersome VMS but who have a high degree of concern regarding their future dementia risk may choose to initiate systemic HT. Before initiating HT in this context, patients should understand that prevention of dementia does not represent an established indication for HT.

VASOMOTOR SYMPTOM TREATMENT

Understanding the duration of VMS, described earlier (p. 476), allows women to make sound decisions regarding treatment. Without question, HT represents the most effective treatment. Based on the safety profile detailed previously, HT represents an appropriate choice for VMS treatment in those aged younger than 60 or those within 10 years of menopause onset (The North American Menopause Society, 2017).

Hormonal Therapy

Estrogen

Although estrogen injections and subdermal pellets to treat VMS are available, serum E_2 levels associated with these formulations are not well characterized. Accordingly, use of FDA-approved oral and transdermal estrogen is recommended (Table 22-4). In the United States, most prescribed systemic estrogens are oral. The most commonly prescribed oral estrogens for VMS treatment are E_2 and CEE, and standard doses are 1.0 mg and 0.625 mg, respectively (American College of Obstetricians and Gynecologists, 2018c). These estrogens are also available in higher and lower doses.

Transdermal estrogen offers the convenience of less frequent administration, with once- or twice-weekly patch changes. All transdermal estrogen formulations use E_2. Preparations in gel, emulsion, and spray are available, however, transdermal patches are most commonly prescribed in the United States. Standard-dose E_2 patches release 0.0375 mg or 0.05 mg of hormone daily, but higher and lower doses are available. All systemic HT products have FDA approval for VMS treatment. The exception is the ultra-low-dose E_2 patch Menostar, which releases 0.014 mg E_2 daily and is approved for osteoporosis prevention.

Common side effects associated with estrogen use include breast tenderness, bloating, and uterine bleeding. Lowering the estrogen dose often reduces these adverse effects, but this may also result in VMS recurrence. Some clinicians start patients on standard-dose estrogen, while others start with a lower dose. Symptom response to a given estrogen dose may not stabilize for several months. Thus, waiting 2 to 3 months before reassessing the response to a dose change is appropriate.

Monitoring serum estrogen levels should not routinely be employed when treating VMS. Occasionally, however, menopausal patients may report inadequate symptoms relief despite increasing doses of estrogen. In this setting, monitoring serum E_2 levels may help. Since serum estrogen levels fluctuate with oral estrogen use, monitoring serum E_2 levels should be reserved for women using transdermal E_2, which is associated with steady-state serum levels. A reasonable target range at menopause is 40 to 100 pg/mL, and levels below this may inadequately relieve VMS (Kaunitz, 2012, 2015).

Progestogens

Progestogens alone have efficacy in treating VMS and may be used in women for whom estrogen is contraindicated. However, most progestogen use involves EPT. In the United States, the progestogens most commonly prescribed are MPA, which is available in 2.5-mg, 5-mg, and 10-mg oral doses, and micronized progesterone, which is available in 100-mg and 200-mg oral doses. Some combined EPT therapies instead use norethindrone acetate, drosperinone, or levonorgestrel (see Table 22-4)

Among women using standard-dose estrogen, continuous progestogens therapy with a 2.5-mg MPA or a 100-mg progesterone dose is sufficient for endometrial protection. Because progesterone has a hypnotic effect, it is best taken at bedtime. Progestogens also may cause dysphoria. Changing the progestogen type, employing sequential rather than continuous progestogen therapy, or adding antidepressant therapy are options. Off-label use of a progestin-releasing intrauterine device, which protects the endometrium while exposing the central nervous system to a lower progestogen level, may be considered (Depypere, 2015; Kaunitz, 2015). Various oral and transdermal EPT formulations are available (see Table 22-4).

Bazedoxifene

Throughout the body, estrogen may bind with its receptors, estrogen receptor α (ERα) and estrogen receptor β (ERβ). These receptors vary in their distribution (Fig. 22-6). Selective estrogen-receptor modulators (SERMs) are agents that after binding to the estrogen receptor may act as an estrogen agonist or antagonist (Fig. 22-7).

Bazedoxifene (BZA) is one such SERM. It is combined with CEE as oral Duavee, which was FDA-approved in 2014 for the treatment of moderate to severe menopausal VMS and prevention of postmenopausal osteoporosis in women with an intact uterus (Lobo, 2009). This combination is called a *tissue-selective estrogen complex (TSEC)*. This TSEC offers the benefits of CEE plus the SERM's ability to offset estrogen stimulation of the endometrium and breast (Pinkerton, 2014). Accordingly, this TSEC offers a progestogen-free alternative for women with a uterus.

By itself, BZA slows bone mineral density loss, increases the number of hot flashes, and raises VTE risks. In contrast, a 20-mg BZA/0.45-mg CEE combination blunts bone mineral

TABLE 22-4. Selected Systemic Hormonal Preparations for the Treatment of Menopausal Vasomotor Symptoms

Preparation	Generic Name	Brand Name	Available Strengths
Estrogen			
Oral[a]	CEE	Premarin	0.3, 0.45, 0.625, 0.9, or 1.25 mg
	17β-Estradiol	Estrace[b]	0.5, 1.0, or 2.0 mg
	Estradiol acetate	Femtrace	0.45, 0.9, or 1.8 mg
	10 synthetic estrogens	Enjuvia	0.3, 0.45, 0.625, 0.9, or 1.25 mg
Transdermal Patch	17β-Estradiol	Alora[b]	0.025, 0.05, 0.075, or 0.1 mg/d (patch applied twice weekly to abdomen or buttock; 8 patches/box)
	17β-Estradiol	Climara[b]	0.025, 0.0375, 0.05, 0.06 0.075, or 0.1 mg/d (patch applied to abdomen or buttock weekly; 4 patches/box)
	17β-Estradiol	Menostar[b]	14 µg/d (patch applied to abdomen weekly; 4 patches/box)
	17β-Estradiol	Vivelle-Dot[b]	0.025, 0.0375, 0.05, or 0.075, 0.1 mg/d (patch applied twice weekly to abdomen; 8 patches/box)
		Minivelle[b]	(0.025, 0.0375, 0.05, 0.075 and 0.1 mg/d) (patch applied twice weekly to abdomen; 8 patches/box)
Transdermal Gel/Spray	17β-Estradiol	EstroGel[b]	1 metered dose of gel (0.06%) applied to arm daily (64 doses per 93-g can)
	17β-Estradiol	Estrasorb[b]	Gel from 2 packets applied to legs daily (56 packets/carton)
	17β-Estradiol	Divigel[b]	0.25-, 0.5-, or 1-mg packets Gel from 1 packet applied to thigh daily (30 packets/carton)
	17β-Estradiol	Elestrin[b]	1 metered dose of gel (0.06%) applied to arm daily (30 doses per 35-g container)
	17β-Estradiol	Evamist[b]	1 to 3 metered-dose sprays to forearm daily (56 doses per pump)
Vaginal	Estradiol acetate	Femring	0.05 or 0.1 mg/d (inserted for 90 days)
Progestogen			
Oral[a]	MPA	Provera	2.5, 5.0, or 10.0 mg
	Micronized progesterone	Prometrium[b]	100 or 200 mg (in peanut oil) (12–14 days per cycle or nightly)
Vaginal	Progesterone	Prochieve 4%[b]	45 mg
Combination preparations			
Oral sequential[a]	CEE + MPA	Premphase	0.625 mg CEE (red) plus 0.625 mg CEE/5.0 mg MPA (blue) (28 pills per pack; 14 red & 14 blue)[c]
Oral continuous[a]	CEE+ MPA	Prempro	0.3 mg CEE/1.5 mg MPA, or 0.45 mg CEE/1.5 mg MPA, or 0.625 mg CEE/2.5 mg MPA, or 0.625 mg CEE/5 mg MPA (28 pills per pack)
	17β-Estradiol + drospirenone	Angeliq	1 mg E_2/0.5 mg drospirenone (28 pills per pack)
	17β-Estradiol + NETA	Activella	1 mg E_2/0.5 mg NETA, or 0.5 mg E_2/0.1 mg NETA (28 pills per pack)
	Ethinyl estradiol + NETA	Femhrt	2.5 µg EE/0.5 mg NETA, or 5 µg EE/1 mg NETA (28 pills per pack)
	17β-Estradiol +100 mg progesterone	Bijuva[b]	1 mg E_2/100 mg progesterone (30 capsules per pack)
Transdermal continuous	17β-Estradiol + LNG	Climara Pro	0.045 mg/d E_2+ 0.015 mg/d LNG (patch applied weekly; 4 per carton)
	17β-Estradiol + NETA	CombiPatch	0.05 mg/d E_2+ 0.14 mg/d NETA, or 0.05 mg/d E_2+ 0.25 mg/d NETA (patch applied twice weekly to abdomen; 8 per carton)
TSEC[a]	CEE + BZA	Duavee	0.45 mg/d CEE + 20 mg BZA

[a]One pill daily.
[b]Considered a bioidentical preparation.
[c]The first 14 pills contain estrogen and the subsequent pills (15 through 28) contain estrogen with progestin.
BZA = bazedoxifene; CEE = conjugated equine estrogen; LNG = levonorgestrel; MPA = medroxyprogesterone acetate; NETA = norethindrone acetate; TSEC = tissue-selective estrogen complex.

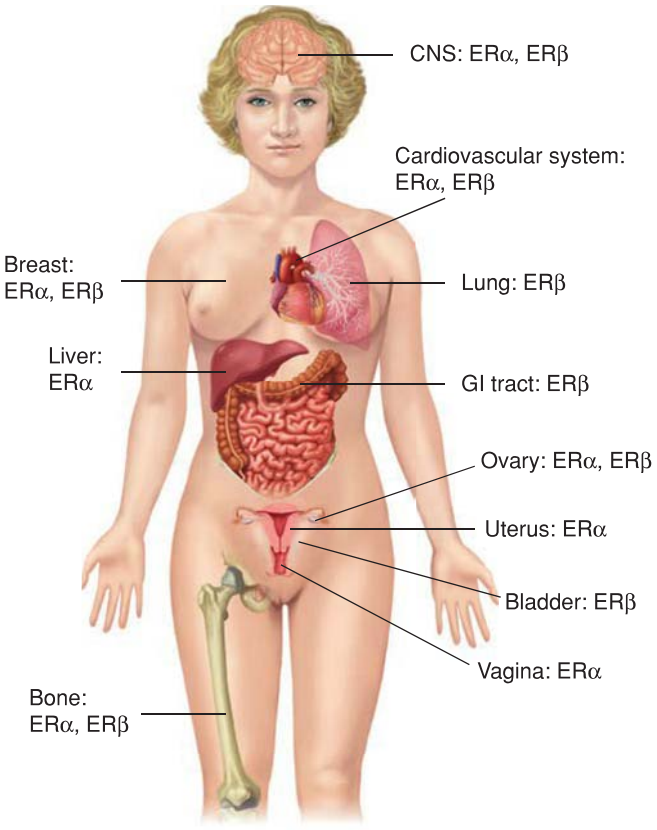

FIGURE 22-6 The presence of estrogen receptor α and estrogen receptor β vary by organ type. Some examples are shown here.

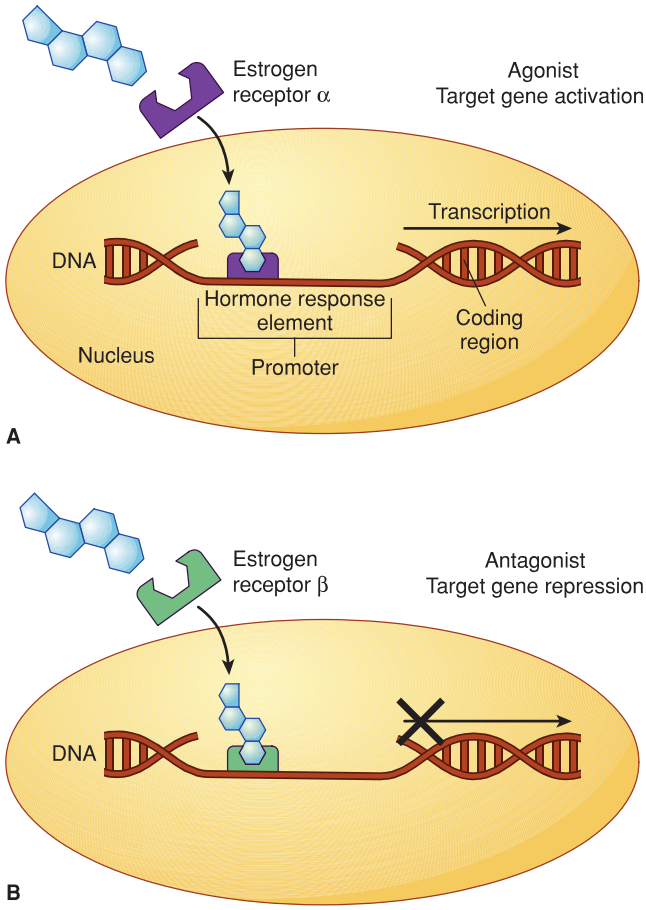

FIGURE 22-7 Selective estrogen-receptor modulator (SERM) action. **A.** A given SERM may act as an agonist in one tissue type to promote DNA transcription. **B.** In a different tissue, that same SERM may act as an antagonist to block transcription of a target gene.

density loss and hot flash incidence but does not raise VTE rates compared with EPT using CEE plus MPA.

In the randomized Selective estrogens, Menopause, and Response to Therapy (SMART-2) trial, BZA/CEE reduced hot flash frequency by 74 percent at week 12 compared with a 51-percent reduction from placebo (Pinkerton, 2009b). A secondary efficacy analysis of SMART-2 data assessed sleep parameters and health-related quality of life in 318 women experiencing >7 moderate to severe hot flashes daily. Time to fall asleep, sleep disturbance, and sleep adequacy were improved with BZA/CEE compared with placebo. This dose also significantly improved the vasomotor function score and the Menopause-Specific Quality of Life (MENQOL) questionnaire score compared with placebo (Utian, 2009). In the SMART-V trial, BZA/CEE was compared with 1.5 mg MPA/0.45 mg CEE. BZA/CEE users achieved comparable relief of hot flashes and prevention of bone loss, but experienced less breast tenderness and uterine bleeding. The rates of breast tenderness, breast density changes, and uterine bleeding were similar to placebo (Pinkerton, 2013). Long-term safety and efficacy data are needed, but this TSEC appears to be neutral on the endometrium and breast in clinical trials up to 2 years.

Potential candidates for BZA/CEE include women with an intact uterus wishing to use systemic HT but concerned regarding its safety with respect to breast cancer. In addition, women who experience unpleasant mood symptoms with progestogens or prefer to avoid bleeding may appreciate that BZA/CEE is progestogen-free.

Bioidentical Hormones

Some women believe that conventional FDA-regulated pharmaceutical estrogens and progestogens present unacceptable risks. Ironically, more is known about the absolute risks and benefits of HT than almost any other class of drugs. Although prescriptions for estrogen and progestogens have declined since publication of WHI results, the use of *bioidentical hormones* that are not FDA approved has grown. This term, invented by marketers, is often used to describe custom-compounded HT products but has no clear scientific meaning (Shifren, 2014). Custom compounding of HT may combine several hormones that include estradiol, estrone, estriol, testosterone, dehydroepiandrosterone (DHEA), and progesterone. They often use nonstandard routes of administration such as subdermal implants or creams. Some of the hormones are not FDA approved (estriol), and some compounded therapies contain nonhormonal dyes or preservatives. Moreover, these formulations have not been tested for efficacy or safety; product information is not consistently provided to women with their prescription; and batch standardization may be uncertain (Santoro, 2016b). Thus, these preparations cannot

be assumed to be safer than conventional pharmaceutical estrogen or progestogens. Several organizations note that conventional FDA-approved HT products are preferred (American College of Obstetricians and Gynecologists, 2018a; The North American Menopause Society, 2017).

In conjunction with bioidentical hormones, salivary hormone testing to assist with hormone level adjustment is not recommended due to inter- and intra-patient variability (Lewis, 2002; Zava, 1998). For women who request bioidentical hormone therapy, FDA-approved bioidentical hormone therapies are noted in Table 22-4.

Nonhormonal Central Nervous System Agents

Pharmacologic therapies with supported efficacy for hot flash rate reduction include selective serotonin-reuptake inhibitors (SSRIs) and serotonin norepinephrine-reuptake inhibitors (SSNIs), gabapentinoids (gabapentin and pregabalin), and clonidine (Table 22-5). In general, these reduce hot flash frequency and severity by 50 to 60 percent (Pinkerton, 2019; Sideras, 2010).

Of these, low-dose, 7.5-mg paroxetine mesylate is the only one that is FDA-approved therapy for VMS. Paroxetine, escitalopram, and venlafaxine are the best-studied for this indication, and their doses for VMS are lower than those used for psychiatric conditions. These agents may cause dizziness, headache, and nausea, but the incidence is lower than with higher psychiatric doses. When prescribing 7.5 mg of paroxetine, initial dose escalation is not needed nor is a cessation taper. Of other caveats, fluoxetine and paroxetine are contraindicated in women taking tamoxifen due to concomitant effects on the cytochrome P450 enzyme system, the liver enzymes that metabolize them. Instead, in this setting, venlafaxine, desvenlafaxine, gabapentin, and pregabalin are more suitable for VMS treatment, as is escitalopram, which has less effect on P450 enzymes.

Gabapentin for VMS may begin with a 100-mg oral dose three times daily and can escalate to 300 mg three times daily. For women with night-time symptoms, a 300-mg gabapentin dose at night can be increased to 600 mg after 2 weeks. For pregabalin, the recommended starting dose is 50 mg orally daily and is advanced to 75 mg twice daily. Both of these gabapentinoids may cause dizziness and sedation, which are dose-related (Sideras, 2010).

Clonidine is FDA approved for hypertension. It is used off label infrequently for VMS relief due to associated orthostatic hypotension and other side effects.

Although additional data are needed, potential new therapies include oxybutynin and neurokinin B–receptor antagonists. In the largest randomized trial of oxybutynin, 150 women were provided placebo or oral oxybutynin in 2.5-mg or 5.0-mg doses twice daily. Oxybutynin treatment at both doses lowered a hot flash composite score compared with placebo (Leon-Ferre, 2018). Prominent side effects were dry mouth and difficulty urinating, which are typical of this anticholinergic drug (Chap. 23, p. 532). With neurokinin B–receptor antagonists, both hot flash rates and sleep disturbances are improved (Pinkerton, 2019). Both agents appear to be as effective as HT and may represent a significant advance in nonhormonal treatment if safety and long-term efficacy data are positive.

TABLE 22-5. Nonhormonal Agents Used for Vasomotor Symptoms[a]

Prescription (brand name)	Dose[b]
SSRI	
Paroxetine mesylate (Brisdelle)[c]	7.5 mg
Paroxetine (Paxil)[c]	20 mg
Venlafaxine (Effexor XR)	37.5–75 mg
Citalopram (Celexa)	20 mg
Escitalopram (Lexapro)	10–20 mg
Sertraline (Zoloft)	50 mg
Fluoxetine (Prozac, Sarafem)[c]	20 mg
SNRI: Desvenlafaxine (Pristiq)	100 mg–150 mg
Clonidine (Catapres)	0.1 mg transdermal
Gabapentin (Neurontin)	600–900 mg (divided doses)
Pregabalin (Lyrica)	900 mg (divided doses)

[a]Off-label use except for paroxetine mesylate.
[b]Oral daily dosing.
[c]Avoid tamoxifen users, inhibitors of CYP2D6.
SNRI = selective norepinephrine- reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

Over-the-Counter Supplements

Over-the-counter herbal formulations, particularly soy, red clover, and black cohosh, are widely used to treat VMS. Unfortunately, randomized trials have not found these supplements to be more effective than placebo in treating VMS (Newton, 2006). One metaanalysis noted that phytoestrogen supplementation modestly reduces hot flash frequency but not night sweats (Franco, 2016). Another evaluating soy isoflavones found a lowered incidence and/or severity of hot flashes (Daily, 2019). That said, more robust research is needed to clearly establish benefits.

Lifestyle Changes

Practical, nonpharmacologic steps to relieve VMS include using fans, lowering ambient room temperatures, layering clothing, consuming cool beverages, and avoiding triggers such as alcohol, caffeine, and spicy foods. Weight loss, non-sweat-inducing exercise, and mindfulness stress-reducing therapies may provide quality-of-life benefits and possibly hot flash reduction. Unfortunately, the efficacy of acupuncture, exercise, yoga, paced respiration, and relaxation training in treating VMS has not been robustly documented (Kaunitz, 2015; Pinkerton, 2019). However, a recent analysis from three trials of VMS interventions found that acupuncture, yoga, and wellness education classes all provided similar relief and afforded a 35- to 40-percent reduction in hot flash frequency compared with untreated controls (Avis, 2019). In small trials, hypnosis and cognitive behavioral therapy each lowered VMS frequency. However, both interventions are limited by access to trained providers (Pinkerton, 2019; The North American Menopause Society, 2015).

BONE HEALTH

Bone Structure and Metabolism

The skeleton consists of two bone types. Cortical bone is more compact and is the bone of the peripheral skeleton (arms and legs). Trabecular bone is more porous and is the bone of the axial skeleton, which includes the vertebrae, pelvis, and proximal femur.

Peak bone mass is influenced by genetic and endocrine factors, and opportunity in the younger years for acquiring bone mass is brief. Almost all bone mass in the axial skeleton will be accumulated in young women by late adolescence, so the years immediately following menarche are especially important (Sabatier, 1996; Theintz, 1992). Calcium supplementation in prepubertal and pubertal girls improves bone accrual (Bonjour, 2001; Stear, 2003). Accordingly, osteoporosis prevention with weight-bearing exercise and sufficient vitamin D and calcium intake ideally begins in adolescence (Recker, 1992).

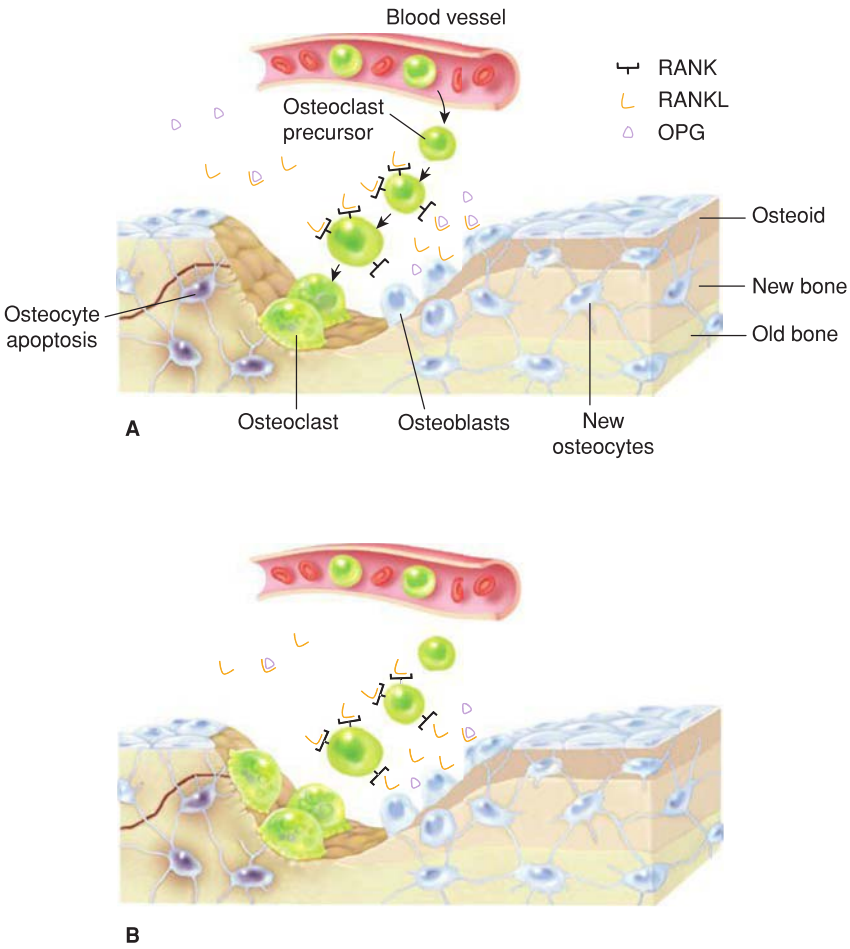

FIGURE 22-8 Bone remodeling. **A.** Osteoclasts resorb matrix, whereas osteoblasts deposit new lamellar bone. Osteoblasts that are trapped in the matrix become osteocytes. Others undergo apoptosis or form new, flattened osteoblast lining cells. Osteoblasts produce the proteins RANKL and OPG. When RANKL binds to RANK, the receptor on the surface of osteoclast progenitor cells, this promotes those cells' development, activity, and survival as osteoclasts. This leads to bone resorption. OPG serves as a counterbalance. OPG binds to RANKL and thereby, RANKL is incapable of binding with RANK to promote osteoclast development. Through this mechanism, bone resorption is limited. **B.** With hypoestrogenism, RANKL production is increased. Excessive levels of RANKL outnumber those of OPG and osteoclast development, and bone resorption is favored.

Following adolescence, bone resorption is normally coupled to bone formation such that positive bone balance is achieved when skeletal maturity is attained, typically at age 25 to 35 years. Thereafter, bone mass declines at a slow, steady rate of approximately 0.4 percent each year. During menopause, in the absence of hormone therapy, this rate rises to 2 to 5 percent per year for the first 5 to 10 years and then slows to 1 percent per year. The subsequent risk of fracture from osteoporosis will depend on bone mass at the time of menopause and the rate of bone loss following menopause (Riis, 1996).

Normal bone is a dynamic, living tissue that is in a continuous process of destruction and rebuilding. The process of bone remodeling involves a constant resorption of bone, carried out by multinucleated giant cells known as *osteoclasts*, and a concurrent process of bone formation, completed by *osteoblasts* (Fig. 22-8).

Activated osteoclasts secrete hydrochloric acid and collagen-degrading enzymes onto the bone surface, resulting in bone mineral dissolution and degradation of the organic matrix. Increased osteoclast activity in postmenopausal osteoporosis is mediated by the receptor activator of nuclear factor (RANK) ligand pathway. In this, RANK, RANK ligand, and osteoprotegerin (OPG) are three major components.

Of these, RANK ligand is expressed by osteoblasts when RANK binds to the RANK receptor on osteoclasts and osteoclast precursors (Bar-Shavit, 2007). Activation of RANK promotes osteoclast formation, function, and survival. RANK ligand is the common regulator of osteoclast activity and ultimately of bone resorption. OPG is also secreted by osteoblasts and is a natural inhibitor of RANK ligand. OPG blocks RANK ligand–mediated activation of RANK to balance bone remodeling (Kostenuik, 2005). RANK ligand is required to mediate osteoclast effects on bone resorption. Cytokines and certain hormones stimulate the expression of RANK ligand by osteoblasts and other cells. Negative regulators of this process include estrogen, which limits the expression of RANK ligand from osteoblasts. Another is OPG, a natural inhibitor of RANK ligand that sequesters and neutralizes the effects of RANK ligand. Estrogen stimulates OPG expression.

In healthy premenopausal women, estrogen limits osteoblast expression of RANK ligand. The OPG binds to RANK ligand to further limit its availability to stimulate osteoclasts. The remaining RANK ligand binds to osteoclast precursors, which fuse and form differentiated osteoclasts for bone resorption. This is followed by the appearance of osteoblasts resulting in bone formation. In sum, resorption and formation are balanced in premenopausal women.

In postmenopausal women, decreased estrogen levels lead to greater RANK ligand

expression, which may overwhelm the natural activity of OPG. Bone resorption follows, and osteoblasts can only partially fill the resulting resorption cavities, leading to a chronic imbalance of formation and resorption resulting in bone loss. Thus, increased RANK ligand after menopause leads to excessive bone resorption and potentially to postmenopausal osteoporosis (Sambrook, 2006).

Osteopenia and Osteoporosis

Clinical Importance

Osteoporosis is a skeletal disorder that progressively reduces bone mass and strength (typically in trabecular bone) and leads to higher fracture rates. *Osteopenia* is a precursor to osteoporosis, and the National Osteoporosis Foundation (2014) estimates that more than 10 million Americans currently have osteoporosis and another 33.6 million have osteopenia of the femoral neck. Of postmenopausal women, 40 to 50 percent experience an osteoporosis-related fracture during their lifetime. Osteoporosis is more common in white and Hispanic women, followed by Native American, Asian, and black women (Barrett-Connor, 2005).

The vertebrae, femoral neck, and wrists are most commonly fractured, and epidemiologic studies estimate that the lifetime risk of common fragility fractures in white women after age 50 approximates 15 percent at each of these sites (Holroyd, 2008; Kanis, 1994). Following a vertebral or hip fracture, postmenopausal women are at higher risk of experiencing another fracture (Lindsay, 2001).

Fractures are associated with significant morbidity and mortality, and a clinical fracture is associated with a twofold increase in mortality risk. The overall mortality rate from femoral neck fracture alone approximates 30 percent. In addition, only 40 percent of those who sustain a femoral neck fracture are capable of returning to their prefracture level of independence. Vertebral fractures are associated with acute and chronic pain, height loss, and deformity, whereas humerus and distal forearm fractures may be associated with substantial disability. Fracture risk rises with age (FitzGerald, 2014). As such, clinicians ideally educate patients regarding bone loss prevention, screen to identify bone loss early, and work with patients to implement effective management plans.

Pathophysiology

A major proportion of bone strength is determined by bone mineral density (BMD), which is grams of mineral per area and volume of bone. However, bone quality, bone strength, and fracture risk are also affected by bone remodeling rates, bone size and geometry, microarchitecture, mineralization, damage accumulation, and matrix quality. Unlike BMD, these parameters are difficult to accurately assess (Kiebzak, 2003).

Primary osteoporosis refers to bone loss associated with aging and postmenopausal estrogen deficiency. As estrogen levels fall after menopause, this steroid's regulatory effect on bone resorption is lost. As a result, bone resorption is accelerated and is usually not balanced by compensatory bone formation. This accelerated bone loss is most rapid in the early postmenopausal years (Gallagher, 2002). If osteoporosis is caused by other diseases or medications, the term *secondary osteoporosis* is used (Stein, 2003).

The amount of bone at any point in time reflects the balance of the osteoblastic (building) and osteoclastic (resorbing) activities (Canalis, 2007). As noted, both aging and a loss of estrogen lead to greater osteoclast activity. Also, less dietary calcium intake or impaired calcium absorption from the gut lowers the serum level of ionized calcium. This results in parathyroid hormone (PTH) secretion, which mobilizes calcium from bone by stimulation of osteoclast activity. Increased PTH levels stimulate vitamin D production. In turn, elevated vitamin D concentrations raise serum calcium levels by several effects: (1) stimulation of osteoclasts to remove calcium from bone, (2) increased intestinal calcium absorption, (3) enhanced renal calcium reabsorption, and (4) reduced PTH production by the parathyroid glands.

In healthy premenopausal women, this series of events leads to increased serum calcium levels, and PTH levels return to normal. In menopausal women, estrogen deficiency creates a greater responsiveness of bone to PTH. Thus, for any given PTH level, relatively more calcium is removed from bone, leading to bone loss and loss of microarchitecture for both trabecular and cortical bone.

Diagnosis

The primary clinical tool to identify bone loss is an assessment of BMD using dual-energy x-ray absorptiometry (DEXA) of the lumbar vertebrae, and femoral neck (Fig. 22-9) (Marshall, 1996). The lumbar vertebrae contain primarily trabecular bone, which has a faster bone remodeling rate. Therefore, early rapid bone loss can be determined by evaluation of this site. Cortical bone is denser bone and is most abundant in the long-bone shafts of the appendicular skeleton. The greater trochanter and femoral neck contain both cortical and trabecular bone, and these sites are ideal for the prediction of femoral neck fracture risk in older women (Miller, 2002). Alternatively, in those with prior back surgery or bilateral hip replacement, appendicular BMD of the radius is used.

Normative BMD values for sex, age, and ethnicity have been determined. For diagnostic purposes, results of BMD testing are reported as *T-scores*. These measure in standard deviations (SDs) the variance of an individual's BMD from that expected for a person of the same sex at peak bone mass (25 to 30 years). A T-score of –2.0 in a woman, for example, means that her BMD is two SDs below the average peak bone mass for a young woman. T-scores are used to make the diagnosis of osteoporosis in postmenopausal women. Definitions are found in Table 22-6 (National Osteoporosis Foundation, 2014). The standard criteria for diagnosing postmenopausal osteoporosis is a T-score of −2.5 or lower at the lumbar spine, femoral neck, or total hip by DEXA testing (Cosman, 2014). The fourth category, *severe osteoporosis*, describes patients who have a T-score below –2.5 and who have also suffered a fragility fracture. A

TABLE 22-6. World Health Organization Criteria for Bone Disease Based on Bone Mineral Density (BMD)

Normal BMD: T-score between +2.5 and −1.0
Osteopenia: T-score between −1.0 and −2.5
Osteoporosis: T-score at or below −2.5
Severe osteoporosis: T-score at or below −2.5 with one or more fractures

fragility fracture is one that results from a fall from a standing or lower height and does not stem from major trauma.

Patients are also assigned a *Z-score*, which is the SD between the patient's measurement and the average bone mass for a patient with the same age and weight. The Z-score is the preferred manner of expressing BMD results in premenopausal women. Z-scores lower than –2.0 require diagnostic evaluation for *secondary osteoporosis* (Faulkner, 1999). Similarly, initial evaluation of any patient with osteoporosis should include checking for causes of secondary osteoporosis (Table 22-7).

BMD represents the most readily quantifiable fracture risk predictor for those who have not yet suffered a fragility fracture. For each SD of BMD below a baseline level (either mean peak bone mass or mean for the reference population of the person's age and sex), the fracture risk approximately doubles (National Osteoporosis Foundation, 2002).

Recognizing the difficulty in measuring bone quality accurately, the World Health Organization (WHO) developed the Fracture Risk Assessment Tool (FRAX) to assess an individual's 10-year fracture risk from age 40 to 90 years. The algorithm is applicable only for patients who have not received pharmacotherapy. The FRAX tool is accessible online and is available for multiple countries/ethnicities and in different languages (http://www.shef.ac.uk/FRAX/). This online tool incorporates 11 risk factors including prior fractures, parental hip fracture history, age, gender, BMI, ethnicity, smoking, alcohol use, glucocorticoid use, rheumatoid arthritis, and secondary osteoporosis. These are combined with the femoral neck bone density (raw or T-score) to calculate the 10-year fracture risk. This WHO site offers downloadable charts for calculating fracture risks using BMD or BMI (as a surrogate for BMD). The FRAX tool identifies patients who might benefit from pharmacotherapy and is most useful for assessing those with osteopenia. One screening and management algorithm from the American College of Obstetricians and Gynecologists (2019a) incorporates FRAX probability values (Fig. 22-10).

TABLE 22-7. Common Secondary Causes of Osteoporosis and Recommended Testing

Primary hyperparathyroidism	Serum levels of: parathyroid hormone, calcium, phosphorus, alkaline phosphatase
Secondary hyperparathyroidism from chronic renal failure	Renal function tests
Hyperthyroidism or excess thyroid hormone treatment	Thyroid function tests
Increased calcium excretion	24-hour urine collection for calcium and creatinine concentrations
Hypercortisolism, alcohol abuse, and metastatic cancer	Careful history and when indicated appropriate laboratory studies
Osteomalacia	Serum levels of: calcium, phosphorus, alkaline phosphatase, 1,25-dihydroxyvitamin D

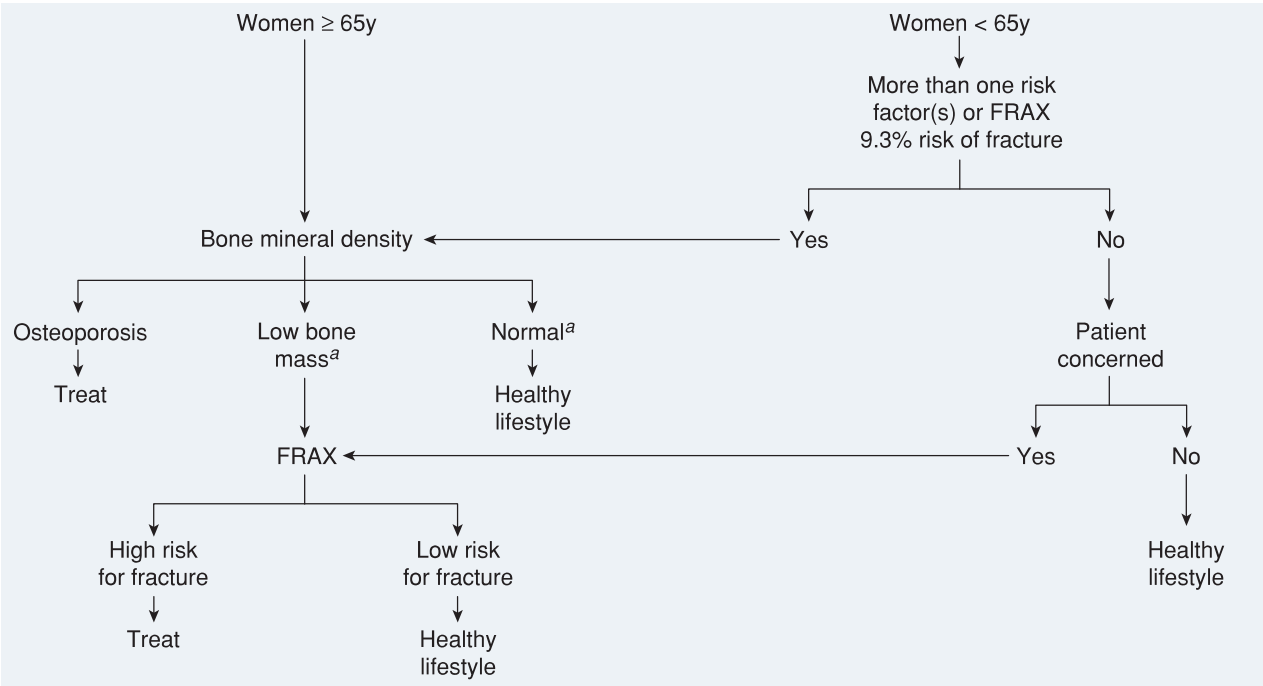

FIGURE 22-10 Screening and treatment algorithm. [a]Prior fragility fracture is an indication for treatment regardless of bone densitometry findings. Those at highest risk are ideally referred to an osteoporosis specialist. (Reproduced with permission from American College of Obstetricians and Gynecologists, 2019a.)

TABLE 22-8. Osteoporosis Risk Factors

Major Risk Factors	Minor Risk Factors
Age >65 years	Rheumatoid arthritis
Low bone mineral density	History of clinical hyperthyroidism
Vertebral compression fracture	Chronic anticonvulsant therapy
Fragility fracture after age 40	Low dietary calcium intake
Family history of osteoporotic fracture	Smoker
Systemic glucocorticoid therapy for >3 months	Excessive alcohol intake
Malabsorption syndrome	Excessive caffeine intake
Primary hyperparathyroidism	Weight <57 kg
Propensity to fall	>10 percent weight loss at age 25
Osteopenia apparent on radiography	Chronic heparin therapy
Hypogonadism	Aromatase inhibitors
Early menopause (before age 45)	

Prevention

As predictors of osteoporotic fracture, the most important factors are listed in Table 22-8. Risk factors for osteoporotic fracture are additive and are considered in the context of baseline age and sex-related fracture risk. For example, a 55-year-old woman with low BMD is at significantly less risk than a 75-year-old woman with the same low BMD. Similarly, a woman with low BMD and a prior fragility fracture is at considerably greater risk than another person with the same low BMD and no prior fracture. Any key risk factor ideally prompts further assessment and possibly active intervention, such as calcium and vitamin D therapy coupled with weight-bearing exercise or pharmacologic therapy (Table 22-9) (National Osteoporosis Foundation, 2014).

Nonmodifiable Factors. Age is a major fracture risk factor. The 10-year probability of experiencing a fracture of forearm, humerus, vertebra, or femoral neck increases as much as eightfold between ages 45 and 85 years for women (Kanis, 2001). Osteoporotic fractures occur most commonly in women older than 65 years. Medical interventions are effective only in preventing fractures in populations with an average age older than 65 years. However, most currently approved osteoporosis therapies prevent or reverse bone loss if initiated at, or soon after, age 50. Therefore, women at high risk for bone loss or with prior fragility fracture are included in those for whom BMD testing is recommended.

A prior fragility fracture places a person at a 1.5- to 9.5-fold higher risk for another fracture, depending on age at assessment, number of prior fractures, and prior fracture site (Melton, 1999). Vertebral fractures are the best studied, and a prior vertebral fracture raises the risk of a second such fracture at least fourfold. In the placebo group of a major clinical trial, 20 percent of those who experienced a vertebral fracture during the study had a second vertebral fracture within 1 year (Lindsay, 2001). Vertebral fractures also indicate vulnerability at other skeletal sites.

Persons of any ethnicity can develop osteoporosis, but data from the Third National Health and Nutrition Examination Survey (NHANES III) show the highest risk among non-Hispanic white and Asian women and lowest among non-Hispanic black women. Racial and ethnic differences are important because fracture rates do not always correlate with BMD across ethnic groups. For example, Chinese American women typically have lower BMD than white American women, but

TABLE 22-9. General Guidelines for Prevention of Osteoporosis in Postmenopausal Women

Counsel on osteoporosis risks
Check for secondary causes (Table 22-7)
For women 51 years and older, encourage diet containing calcium 1200 mg daily and vitamin D 800–1000 IU daily. Add supplement if diet is incomplete; emphasize dietary calcium over supplements
Recommend regular weight-bearing and muscle-strengthening exercise
Advise against tobacco smoking and excess alcohol intake
Assess for fall risks and modify as possible
Measure height annually
In women ≥65 years, recommend BMD testing
In postmenopausal women aged 50–65 years, recommend BMD testing based on the risk factor profile (Table 22-8)
In those >50 years with a new fracture, recommend BMD testing to determine degree of disease severity
For patients on pharmacotherapy, perform BMD testing 2 years after initiating therapy and every 2 years thereafter. However, testing frequency may be tailored to clinical situations

BMD = bone mineral density.

lower rates of femoral neck and forearm fracture (Walker, 2011). It is postulated that greater cortical density and thicker trabeculae compensate for fewer trabeculae in smaller bones. Thus, both BMD and microarchitecture appear to play distinct roles in fracture vulnerability (American College of Obstetricians and Gynecologists, 2019a).

Genetic influence on osteoporosis and BMD is important, and heredity is estimated to account for 50 to 80 percent of BMD variability (Ralston, 2002; Sigurdsson, 2008). The Study of Osteoporotic Fractures identified maternal femoral neck fracture as a predictor for similar fracture in a population of elderly women (Cummings, 1995).

Modifiable Factors. Of these, exercise and fall prevention are primary. These are discussed with other preventive steps on page 495.

Therapy with glucocorticoids lasting more than 2 to 3 months is a major risk factor for bone loss and fracture, particularly among postmenopausal women. A chronic daily dose of prednisone ≥5 mg serves as the threshold for assessment and clinical intervention to prevent or treat glucocorticoid-induced osteoporosis (National Osteoporosis Foundation, 2014). Other medications associated with bone loss include anticonvulsants (phenytoin), anticoagulants (heparin), depot MPA, chemotherapeutic drugs, gonadotropin-releasing hormone agonists, cyclosporine A, tacrolimus, and lithium.

Breast cancer survivors may be at higher risk for bone loss. Reasons include surgery- or chemotherapy-induced early menopause or the lowered estrogen levels seen with aromatase inhibitors.

Osteoporosis Screening. After risk assessment, BMD measurement helps confirm osteoporosis and determine disease severity. BMD testing by DEXA should be performed in postmenopausal women: (1) aged ≥65 years, (2) with one or more risk factors for osteoporosis, or (3) who have sustained fractures (Camacho, 2016; Cosman, 2014; The North American Menopause Society, 2010). Screening is considered for perimenopausal women if they have a specific risk factor such as prior low-trauma fracture, low BMI, or medication known to accelerate bone loss. Many vertebral fractures are asymptomatic, and vertebral imaging is recommended for women aged ≥70 years with a T-score ≤–1.0 or those 65 to 69 years with a score ≤–1.5 (National Osteoporosis Foundation, 2014).

OSTEOPOROSIS TREATMENT

Indications

The primary goal of osteoporosis treatment is fracture prevention in women who have low BMD or additional fracture risks (see Fig. 22-10). Toward this end, therapy aims to stabilize or increase BMD. Treatment includes lifestyle changes and often pharmacologic therapy. The key lifestyle modifications that can decrease fracture risks in postmenopausal women include regular weight-bearing exercise and a balanced diet with adequate calcium and vitamin D. Patients ideally maintain normal body weight and avoid smoking, excessive alcohol intake, and fall risks (Christiansen, 2013).

With pharmacologic therapy, several organizations recommend starting therapy for: (1) postmenopausal women with total hip, femoral neck, or lumbar spine T-scores at or below –2.5; (2) those with an osteoporotic vertebral or hip fracture; (3) those with a prior fragility fracture; and (4) those with a high FRAX fracture probability. For the last, a 10-year major osteoporotic fracture risk ≥20 percent or a hip fracture risk ≥3 percent serves as a threshold (Camacho, 2016; Cosman 2014). Prevention or treatment is consider for postmenopausal women with total hip or spine T-scores from –1.0 to –2.5 with additional fracture risk factors (see Table 22-8).

Drugs prescribed for fracture prevention are those that (1) reduce bone resorption, termed *antiresorptive agents*, or (2) stimulate bone formation, termed *anabolic agents*. Estrogen, SERMs, bisphosphonates, denosumab, vitamin D, and calcitonin each have antiresorptive properties to halt bone loss, and most also increase BMD. These act most quickly on bone that has high trabecular content and rapid turnover, such as the vertebrae. Alternatively, for the hip, therapy-related gains may be delayed because the hip contains approximately 50 percent trabecular and 50 percent cortical bone.

Anabolic agents include teriparatide and abaloparatide, which are PTH analogues that act as agonists at the PTH receptor (Miller, 2016). In contrast, romosozumab inhibits the activity of the bone protein sclerostin. In general, anabolic agents are prescribed by skeletal-health specialists, including medical endocrinologists and rheumatologists.

For osteoporosis, each agent differs in its indication for prevention, for treatment, or both. HT is indicated for the prevention of osteoporosis. Bisphosphonates and SERMs are prevention or treatment options. Calcitonin is used rarely, as other agents are more effective. Denosumab is a monoclonal antibody against RANK ligand and approved for osteoporosis treatment. PTH-receptor agonists and the new sclerostin inhibitor are approved for treatment of osteoporosis in women at high risk of fracture.

Hormonal Options

Estrogen and Progestogens

HT slows the bone resorption rate, which results in a BMD increase (Wells, 2002). In observational studies, HT reduces osteoporosis-related fracture rates by approximately 50 percent when started soon after menopause. Continued long term, HT significantly lowers fracture rates in women with established disease (Tosteson, 2008). Moreover, the WHI trials confirmed a significant 34-percent reduction in hip fracture rates in a healthy low-fracture-risk population of postmenopausal women receiving HT (Jackson, 2006b; The Women's Health Initiative Steering Committee, 2004).

BMD responses do not vary among estrogen preparations or administration routes. Even very low estrogen doses combined with calcium and vitamin D produce significant BMD improvement compared with placebo (Ettinger, 2004; Prestwood, 2003). Specifically, 0.5-mg doses of oral E_2; 0.3-mg doses of CEE; or a transdermal estradiol patch delivering as little as 0.014 mg/d are effective as women are further from menopause. With early menopause, higher doses may be needed.

Some study results suggest that fracture protection wanes rapidly, as significant bone loss may be seen following HT discontinuation. However, in the WHI, higher fracture rates were

not seen after stopping HT (Watts, 2017). Some guidelines recommend HT to prevent bone loss for women with bothersome menopausal symptoms or for women who carry a high fracture risk but who are not candidates for alternative therapies (Camacho, 2016; The North American Menopause Society, 2017). In general and discussed earlier (p. 479), systemic HT initiation is not recommended for women older than 60 or for those 10 years beyond menopause due to associated CHD risks. Fracture risk and the potential need for an alternative therapy should be assessed before women discontinue HT.

Bazedoxifene Formulations

The 20-mg BZA/0.45-mg CEE formulation (Duavee) is indicated for VMS and postmenopausal bone loss prevention. In the randomized SMART trials noted earlier (p. 484), the adjusted mean percentage BMD change in the lumbar spine from baseline to 24 months significantly rose in those taking this BZA/CEE formulation compared with women using placebo (Lindsay, 2009). Findings were similar for total hip BMD.

Raloxifene

In postmenopausal women, this SERM is FDA approved to prevent and treat osteoporosis and to reduce the risk of invasive breast cancer. It activates estrogen receptors in the bone but does not appear to activate those in the breast or uterus.

Raloxifene appears most appropriate for prevention and treatment of vertebral disease. Raloxifene (60 mg/d) prevents vertebral fracture but does not prevent nonvertebral ones (Delmas, 2002; Ettinger, 1999). In addition to its bone effects, raloxifene reduces risk of breast cancer in high-risk women (US Preventive Services Task Force, 2019).

Of side effects, hot flashes are associated with raloxifene therapy, although the incidence is low (Cohen, 2000). Raloxifene use does raise the VTE risk and is contraindicated in patients with prior VTE (Delmas, 2002).

Nonhormonal Antiresorptive Agents

Bisphosphonates

Four bisphosphonates are currently available and include alendronate, risedronate, ibandronate, and zoledronate. The first three are taken orally, but zoledronate is an intravenous infusion. These agents chemically bind to calcium hydroxyapatite in bone (Fig. 22-11). They decrease bone resorption by blocking the function and survival but not the formation of osteoclasts (Diab, 2012; Russell, 2008).

The oral bisphosphonates display poor bioavailability and therefore are taken on an empty stomach with adequate water for proper dissolution and absorption. These agents have a favorable overall safety profile, and adverse event rates are comparable with placebo (Black, 1996; Harris, 1999). However, bisphosphonates may cause upper gastrointestinal inflammation, ulceration, and bleeding (Lanza, 2000). Thus, to aid delivery to the stomach and reduce esophageal irritation, dosing instructions are reinforced with each patient. First, bisphosphonates are taken in the morning after fasting and with a full glass of water. During the 30 minutes after administration, no other food or beverages are consumed. Last, for all immediate

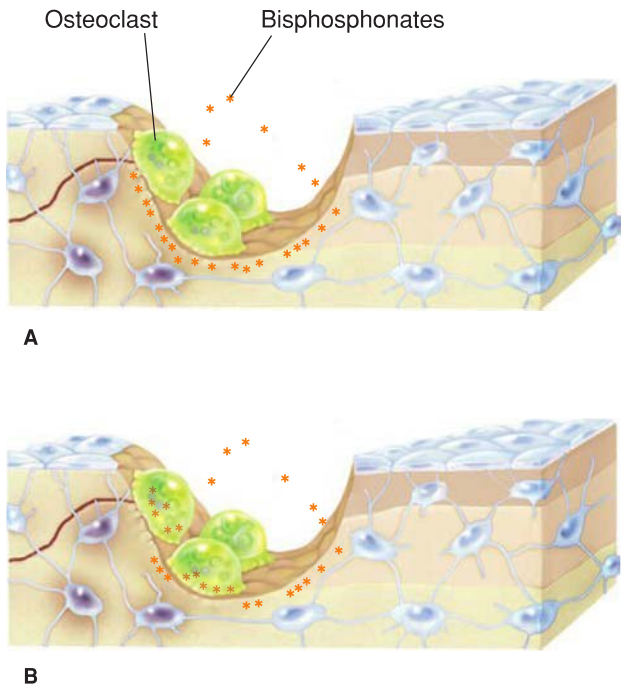

FIGURE 22-11 Bisphosphonates reduce fractures by suppressing bone resorption by osteoclasts. The molecular structure of the bisphosphonates is analogous to that of the naturally occurring pyrophosphates. **A.** Bisphosphonate concentration is increased eightfold at sites of active bone resorption. **B.** The bisphosphonates enter osteoclasts and reduce resorption through inhibition of farnesyl pyrophosphate synthase. Inhibition of this enzyme leads to disruption of osteoclast attachment to the bone surface. This halts resorption and promotes early osteoclast cell death.

release bisphosphonates, women must remain upright (sitting or standing) for at least 30 minutes after ingesting the drug. An enteric-coated delayed-release formulation of risedronate (Atelvia) is taken immediately after breakfast with at least 4 ounces of water, and similar upright posture is required.

In terms of long-term safety, two uncommon adverse events are osteonecrosis of the jaw (ONJ) and atypical femur fractures (AFFs) (Diab, 2013). ONJ is defined as exposed necrotic bone in the maxillofacial region that fails to heal after 8 weeks. Pain, paresthesia, soft tissue ulceration, and loose teeth are symptoms. ONJ can develop spontaneously but is generally associated with invasive dental procedures. Although described in patients with osteoporosis receiving chronic bisphosphonate therapy, ONJ is much more common in cancer patients receiving higher-dose bisphosphonates (Khosia, 2007).

AFFs are stress fractures that are frequently bilateral, are typically associated with minimal or no trauma, and are heralded by prodromal pain in the fracture region (Dell, 2012). One study found that longer bisphosphonate use (5 to 9 years) led to a greater risk of AFFs compared with shorter use (<2 years) (Meier, 2012). In one review, bisphosphonate exposure was associated with an adjusted risk ratio of 1.70 for AFFs (Gedmintas, 2013).

The risks of these adverse events may increase after 5 years of therapy, although the likelihood remains low. The FDA suggests reevaluating individually the need for continued bisphosphonate therapy beyond 3 to 5 years (Whitaker, 2012). In selected

patients, a "drug holiday" may be considered because of the unique pharmacokinetics of bisphosphonates. These agents accumulate in the skeleton to create a reservoir that continues to be released for months or years after treatment. This provides some residual benefit in terms of fracture reduction after an initial 3- to 5-year therapy course. That said, continuing treatment for 10 years may be a better choice for high-risk patients. If a drug holiday is advised, risk is reevaluated sooner for drugs with lower skeletal affinity. Thus, after a drug holiday, reassessment in high-risk women may be prudent after 1 year for risedronate, 1 to 2 years for alendronate, and 2 to 3 years for zoledronate (Diab, 2014).

Alendronate. This bisphosphonate is administered orally weekly and marketed as Fosamax or Binosto. With Fosamax, a 35-mg weekly dose is indicated for postmenopausal osteoporosis prevention, whereas a 70-mg weekly dose treats affected women. Binosto carries only the indication of osteoporosis treatment and is provided as a 70-mg weekly dose.

Alendronate reduces the risk of vertebral fractures in postmenopausal women with low BMD or osteoporosis (Black, 1996). Alendronate causes a sustained reduction in risk of nonvertebral fracture risk in women with osteoporosis. For example, women who used alendronate for 5 years and then discontinued use for a subsequent 5 years had nonvertebral fracture rates comparable to those of women using the drug for 10 years (Black, 2006; Bone, 2004).

Risedronate. This bisphosphonate effectively treats postmenopausal osteoporosis and prevents both vertebral and hip fractures in women with osteoporosis (Cosman, 2014). Several dosages are available. Actonel is indicated for prevention or treatment, and either a 5-mg daily or a 35-mg weekly dosage is recommended. For treatment with Actonel, a 150-mg monthly dose or a 75-mg dose taken once a month on two consecutive days are other options. Atelvia is a 35-mg time-release oral tablet taken weekly and is FDA indicated solely for postmenopausal osteoporosis treatment.

Ibandronate. This bisphosphonate is FDA approved as Boniva to prevent and treat postmenopausal osteoporosis and has been shown to prevent vertebral fractures in women with osteoporosis (Cosman, 2014). For both indications, a 150-mg oral dose is taken once monthly.

Zoledronate. This bisphosphonate is FDA approved as Reclast to treat postmenopausal osteoporosis, and it lowers vertebral and hip fracture rates in affected women (Cosman, 2014). Zoledronate is a single, yearly intravenous infusion administered over at least 15 min. It may be a choice for women who cannot safely use oral bisphosphonates due to gastroenterologic concerns.

Denosumab

Denosumab (Prolia) is a fully human monoclonal antibody that binds and inhibits RANK ligand (see Fig. 22-8). Osteoclast development and activity is inhibited, which leads to decreased in bone resorption and greater BMD. As a result, it reduces vertebral and hip fracture rates (Cosman 2014, Bone, 2017). Rare cases of AFFs and ONJ may complicate long-term therapy. Rapid bone loss occurs after discontinuation, and case reports describe vertebral fractures after discontinuation of denosumab (Anastasilakis, 2017). This underscores compliance with the scheduled 60-mg subcutaneous injection every 6 months. In addition, initiation of an antiresorptive agent such as a bisphosphonate is considered if denosumab therapy is stopped.

Calcitonin

The polypeptide hormone calcitonin slows bone absorption by inhibiting osteoclasts' resorptive activity. Calcitonin is delivered as an injection or nasal spray (Fortical, Miacalcin). Other available options are more effective than calcitonin in preventing bone loss and fracture. However, calcitonin appears to have an independent analgesic effect on bone, which makes it useful as an adjunct to other therapies for osteoporosis in women with painful, symptomatic fracture (Blau, 2003).

Parathyroid Hormone–Receptor Agonists

The PTH-receptor agonists teriparatide and abaloparatide are anabolic agents that activate osteoblastic bone formation through interactions with the PTH receptor. Teriparatide (Forteo) is given as a 20-μg daily subcutaneous injection for up to 2 years. It is FDA approved to treat postmenopausal women with established osteoporosis who are at high risk for fracture. At low daily doses, the anabolic effects of PTH predominate. This is in contrast to the catabolic effects generally associated with the long-term, higher-dose, chronic exposure to PTH seen in individuals with hyperparathyroidism.

Teriparatide improves bone microarchitecture and enhances bone quality by increasing bone density, turnover, and size (Rubin, 2002). In women with postmenopausal osteoporosis, teriparatide leads to major reductions in vertebral and nonvertebral fracture rates (Neer, 2001). Among women with prior vertebral fractures, teriparatide more effectively reduced fracture risk than risedronate in one randomized trial (Kendler, 2018). With PTH-receptor agonists, the most frequent adverse events are hypercalcemia, dizziness, leg cramps, nausea, and headache. Following therapy, switching to either bisphosphonate or denosumab therapy will preserve BMD (Ebina, 2017; Leder, 2015).

The second anabolic agent, abaloparatide (Tymlos), is a synthetic analogue of parathyroid hormone–related peptide (PTHrP) that has been modified to potentiate its anabolic effect. In one randomized trial of postmenopausal women with osteoporosis, an 80-μg daily subcutaneous abaloparatide injection reduced the relative risk of vertebral, nonvertebral, major osteoporotic, and clinical fractures compared with placebo. The PTH analogue also better lowers the risk of major osteoporotic vertebral and nonvertebral fractures compared with teriparatide (Miller, 2016). Following discontinuation of abaloparatide, substituting alendronate for an additional 6 months improved BMD and reduced fractures (Cosman, 2017).

For both PTH analogues, toxicity studies with rats have shown a higher risk of osteosarcoma. However, bone metabolism differs greatly between rats and humans, and the relevance of these data to humans is unclear. Both products have a black-box warning on their product labeling recommending avoidance of

these agents in those at risk for osteosarcoma. Cumulative use for more than 2 years is not recommended due to the potential for side effects (Tashjian, 2002).

Sclerostin Inhibitor

Romosozumab, a humanized antibody that binds sclerostin, received FDA approval in 2019 to treat postmenopausal women at high risk for fracture. It binds and inhibits the activity of the protein sclerostin, which inhibits activation of osteoblast function. Thus, by blocking sclerostin, romosozumab allows osteoblasts to function. This agent increases bone formation and retards bone breakdown (McClung, 2014).

In clinical trials, romosozumab is more effective than alendronate in preventing vertebral and nonvertebral fractures among women with osteoporosis. Therapy spans 12 months, after which bone effects wane, and should be followed by either denosumab or alendronate (Cosman, 2016; Saag, 2017). Romosozumab carries a black-box warning on its product labeling that describes a potential for increased risks of myocardial infarction, stroke, and cardiovascular death. In clinical trials, ONJ and AFFs also have been reported with romosozumab use.

Therapy Recommendations

First-line therapy for postmenopausal women with osteoporosis includes antiresorptive therapy with a bisphosphonate or denosumab. Women who take bisphosphonates and who are not considered a high risk for fracture may elect a drug holiday, as bisphosphonates have relatively long-term effects in bone. For those receiving denosumab, bone effects are rapidly lost after discontinuation. Thus, a bisphosphonate is recommended after denosumab cessation to maintain BMD gains. For women at high risk for fracture, anabolic agents teriparatide, abaloparatide, and romosozumab provide transient increases in BMD and fracture reduction. These should be followed by antiresorptive treatment with a bisphosphonate or denosumab, again to maintain BMD gains.

Referral to a bone specialist for management is recommended for those at higher risk of fracture. High-risk women include those with severely low T scores (less than –3.0 SD); progressive BMD decline; new vertebral, hip, or fragility fractures; and lack of therapy response. Similarly, referral for evaluation and treatment of secondary osteoporosis or of significant idiopathic osteoporosis in premenopausal women may be considered.

Nonpharmacologic Therapy

Calcium

Nonpharmacologic interventions are cornerstones of osteoporosis prevention and include dietary modifications, exercise programs, fall prevention strategies, and education. The results of studies evaluating effects of calcium and vitamin D supplementation on fracture risk are inconsistent. However, adequate daily calcium intake is essential for bone maintenance. For women aged 31 to 50 years, the recommended dietary reference intake (DRI) is 1000 mg daily, and for those 51 years and older, 1200 mg is recommend daily. Ideally, these DRIs are obtained through diet alone, but supplementation is used to attain these levels if needed (Prentice, 2013; Ross, 2011). Few women meet these goals, and calcium deficiency is widespread. For example, more than 90 percent of women fail to consume enough dietary calcium to meet DRIs put forth by the Institute of Medicine. Although poor calcium intake is observed at all ages, it appears to be most common among older individuals, and <1 percent of women 71 years or older actually meeting recommended goals.

Calcium supplementation combined with vitamin D administration reduces bone loss and fracture risks (Chapuy, 1992; Dawson-Hughes, 1997; Larsen, 2004). Prentice and associates (2013) examined the health benefits and risk of calcium and vitamin D supplementation using WHI data. Again, a substantial hip fracture risk reduction was found. Excess calcium intake is avoided due to enhanced risk of kidney stones, milk alkali syndrome, and possibly cardiovascular events (Bolland, 2008; Jackson, 2006a). Because of concern for potentially greater atherosclerosis risk with calcium supplements, guidelines encourage *dietary* calcium sources to meet recommended amounts.

Vitamin D

The optimal daily vitamin D intake amount and appropriate target levels for serum 25-OH D are unresolved. The vitamin D DRI is 600 IU daily for a postmenopausal woman. For persons at high risk of osteoporosis or who are older than 70 years, 800 IU daily is recommended (Ross, 2011). As with calcium, the prevalence of vitamin D deficiency is high, especially in the elderly and obese. Deficiency leads to poor calcium absorption, secondary hyperparathyroidism, greater bone turnover and bone loss rates, and, if severe, impaired bone mineralization. Vitamin D deficiency also causes muscle weakness that can raise fall rates. Supplementation can reverse many of these effects and significantly lower fall and hip fracture rates (Dawson-Hughes, 1997).

The metabolite 25-hydroxyvitamin D is considered to be the best clinical measure of vitamin D stores (Rosen, 2011). Vitamin D *deficiency* is defined as a serum 25-hydroxyvitamin D level below 10 ng/mL. Vitamin D *insufficiency* is a serum level of 25-hydroxyvitamin D between 10 and 30 ng/mL. Metaanalyses do not support routine supplementation of vitamin D. Moreover, treatment with a very high dose of vitamin D once yearly has been associated with higher fall and fracture rates (Sanders, 2010). The U.S. Preventive Services Task Force (2018b) recommends against daily supplementation with >400 IU of vitamin D and with >1000 mg of calcium for the primary prevention of fractures. For women with a diagnosis of osteoporosis, adequate calcium and vitamin D intake are encouraged.

Diet

A relationship between protein intake and BMD has been reported, but a relationship with either BMD effects or fracture risk are inconsistent (Shams-White, 2017). Using data from the Third National Health and Nutrition Examination Survey (NHANES III), Kerstetter and colleagues (2000) demonstrated a significant association between protein intake and total femur

BMD among non-Hispanic white women aged 50 years and older. Moreover, protein supplementation (20 g/d) five times weekly for 6 months following hip fracture was associated with a 50-percent reduction in femoral bone loss at 1 year compared with placebo. Higher protein intake is also associated with fewer falls in at-risk elderly patients losing weight (Zoltick, 2011).

Healthy diets that provide the daily DRI of protein contain at least 46 g/d for women (Dawson-Hughes, 2002). Notably, excess urinary calcium excretion is observed with the large acid loads delivered by very-high-protein diets (Barzel, 1998).

Caffeine consumption does not appear to influence bone health in postmenopausal women who maintain an adequate daily intake of calcium and vitamin D. However, one longitudinal study showed that even moderate amounts of caffeine (two to three servings of coffee daily) may lead to bone loss in women with low calcium intake (<800 mg/d) (Harris, 1994).

Calcium reabsorption is directly proportional to sodium reabsorption in the renal tubule. Accordingly, greater dietary sodium increases urinary calcium excretion and corresponding biochemical markers of bone turnover. Specifically, a relationship between high sodium intake (>1768 mg/d) and lower BMD is described (Sellmeyer, 2002). This sodium effect appears to be independent of calcium intake and activity levels. As with caffeine, sodium intake moderation is a reasonable precautionary measure until this relationship is fully understood.

Providing magnesium supplements to patients with malabsorption may be warranted, but routine magnesium supplementation is ineffective for fracture prevention. Phytoestrogens have not shown consistent effects on bone and are not recommended for bone protection.

Physical Preventions

Small but statistically significant increases in BMD have been observed in postmenopausal women participating in exercise programs, including aerobic exercise and resistance training (heavy weight with few repetitions). One metaanalysis of 43 trials concluded that lower-limb resistance exercise was most effective for femur neck BMD, and combination-exercise programs most benefitted vertebral BMD (Howe, 2011). Another analysis that focused on walking showed advantages for femur neck BMD accrual (Ma, 2013). Strength training or resistance training is recommended for at least 30 minutes three times per week and includes free weights or resistance bands, walking or jogging, and jumping.

Although BMD may accrue, especially at exercise-directed sites, benefits also extend to lower fall rates (Carter, 2002). Namely, improved balance, stronger muscles, better muscle tone, and stronger, more flexible bone all contribute to fracture prevention.

Falls are responsible for more than 90 percent of hip fractures (Carter, 2002). Sideways falls appear to be the most detrimental and were independently associated with hip fracture in a study by Greenspan and associates (1998). Therefore, assessing women for fall risk and fall prevention are essential for women with osteopenia or osteoporosis.

Falls are associated with general frailty, such as reduced muscle strength, impaired balance, low body mass, and diminished visual acuity (Delaney, 2006; U.S. Preventive Services Task Force, 2018a). Alcohol and sedative drug use are others.

Living conditions are modified to minimize falls by reducing clutter and implementing nonslip tiles, nonskid strips to bath and shower floor, safety bars, rugs with nonskid backing, night lights, wearing shoes with traction, and avoiding slippery or icy sidewalks. Hip protectors have been suggested for those at high risk for falling. However, these appear effective only in supervised long-term care facilities (Santesso, 2014).

GENITOURINARY SYNDROME OF MENOPAUSE

Terminology

High concentrations of estrogen receptors are present in the vaginal mucosa, vulva, bladder, urethra, and pelvic floor of pre- and postmenopausal women (see Fig. 22-6). Hypoestrogenism can lead to deleterious changes in this highly interdependent anatomy.

The term *vulvovaginal atrophy* has been used to describe the constellation of lower reproductive tract changes stemming from hypoestrogenism. However, midlife women may view the word *atrophy* negatively. More importantly, the term fails to adequately emphasize the global genitourinary effects. Accordingly, a consensus panel and national organizations now recommend *genitourinary syndrome of menopause (GSM)* as preferred terminology (Portman, 2014). GSM encompasses the constellation of pathophysiologic signs and symptoms listed in Table 22-10.

Vulvovaginal Changes

Endogenous E_2 causes the vaginal mucosa to become a thick, well-vascularized, rugated surface that supplies adequate lubrication for most premenopausal women. Low estrogen levels cause atrophic changes, in which the vagina shortens, narrows, and loses flexibility. The vaginal mucosa becomes thin and shiny, and rugae are flattened. The introitus may contract,

TABLE 22-10. Genitourinary Syndrome of Menopause Characteristics

Symptoms	Signs
Genital dryness	Labia minora resorption
Poor lubrication	Narrowed introitus
Dyspareunia	Absent hymeneal tags
Postcoital bleeding	Tissue pallor or erythema
Poor arousal, orgasm, desire	Urethral eversion
Vulvovaginal:	Urethral prolapse
irritation, burning, itching	Prominent urethral meatus
Dysuria	Absent rugae
Urinary frequency	Fragile or fissured tissue
Urinary urgency	Petechial hemorrhages
Recurrent urinary tract	Scant vaginal secretions
infection	Poor elasticity

particularly in the absence of penetrative sexual activity, and these changes can diminish lubrication during sexual stimulation. A hypoestrogenic vaginal squamous epithelium thins to only a few cell layers, and parabasal squamous cells outnumber superficial ones. The thin vaginal mucosa becomes friable and prone to bleed even with minimal trauma. Advanced changes resulting from estrogen deficiency lead to inflammation, resulting in what some clinicians refer to as *atrophic vaginitis* (The North American Menopause Society, 2013).

Clinical Findings

GSM symptoms are common during the MT, and the estimated prevalence among menopausal women is 50 percent (Simon, 2018). In a large observational study, vaginal dryness and dyspareunia were two of the most prevalent GSM symptoms (Palma, 2018). Surveys of menopausal women document the high prevalence of these symptoms and underscore their negative effects on sexual function, partner relationships, and quality of life (Kingsberg, 2017; Nappi 2016). Three quarters of women in the United States aged 57 to 74 are sexually active (Crawford, 2018; Lindau, 2007). Although dryness and pain with intercourse are prevalent among midlife women, few seek help. Thus, during well women visits, clinicians ideally ask about GSM symptoms to provide an opportunity for improvement.

Although a characteristic history will suggest GSM, a pelvic examination can exclude other vulvovaginal conditions that may cause similar symptoms, including chronic infections, contact dermatitis, lichen sclerosus, lichen planus, and malignancy. During menopause, the mons pubis and labia majora and minora lose bulk, whereas the urethral meatus may be prominent and erythematous. If introital or vaginal narrowing is present, use of a thin pediatric speculum with a lubricant (Fig. 1-3, p. 4) can minimize patient discomfort. The vaginal mucosa may appear smooth, shiny, and dry. Petechiae can form after minimal blunt pressure from the speculum, and sweeps with a spatula or cotton-tip swab may cause spotting. Vaginal fornices may become attenuated and result in a cervix that is flush with the vaginal apex.

Laboratory assessment is not required to diagnose GSM. However, vaginal pH and the vaginal maturation index (MI) may be informative. To assess pH, a piece of litmus paper is placed on the lateral vaginal wall until it becomes moistened. Premenopausal women without vaginal atrophy typically have a pH $\leq$4.5 unless they have bacterial vaginosis or trichomoniasis. A pH $\geq$4.6, which may be as high as 7, indicates vaginal atrophy.

A specimen to measure the MI may be collected during a vaginal speculum examination at the same time cervical cancer screening is performed. The index report is read from left to right and refers to the percentage of parabasal, intermediate, and superficial squamous cells appearing on a smear, with the total sum of all three values equaling 100 percent (Fig. 22-12) (Randolph, 2005). For example, an MI of 0:40:60 represents 0 percent parabasal cells, 40 percent intermediate cells, and 60 percent superficial cells. This MI reflects adequate vaginal estrogen influence. A shift to the left indicates an increase in parabasal or intermediate cells, which denotes low estrogen effects.

Treatment

Nonhormonal Options

Many women may indicate that they have few if any GSM symptoms or, if present, may choose to not treat them. However, clinicians should counsel affected women that, absent active management, this condition may worsen over time. In women without severe symptoms, over-the-counter water- or silicone-based vaginal lubricants for sexual activity and regular use of long-acting vaginal moisturizers are appropriate (Pinkerton, 2018). In this setting, women are informed that regular sexual activity including penetration by partner or device may help address symptoms and prevent progression. In some women, contraction of the introitus/vagina or vaginismus may prevent penetration. Use of graduated vaginal dilators, sometimes under the guidance of a specialized physical therapist who focuses on pelvic floor disorders, often allows these women to resume or initiate comfortable sexual activity. Initiating low-dose vaginal ET can accelerate progress.

Estrogen Options

Among women using standard-dose systemic HT to treat VMS, symptomatic GSM is uncommon. However, some women will experience vaginal dryness, dyspareunia, or other GSM symptoms during systemic HT use, particularly if lower than standard HT doses are used. In these patients, low-dose vaginal estrogen can be added to systemic HT. Alternatively, a woman using oral or transdermal systemic HT can change to the 3-month systemic vaginal ring (Femring), which releases 0.05 mg/d or 0.10 mg/d of E_2. This treats vaginal and vasomotor symptoms. Importantly, the systemic vaginal estradiol ring (Femring) differs from the 3-month local vaginal ring (Estring), which releases 7.5 μ/d of E_2. The latter is indicated solely for GSM.

Although over-the-counter lubricant and moisturizer use constitutes appropriate initial treatment for women with symptomatic GSM, prescription treatments for GSM are appropriate for inadequately addressed symptoms. Low-dose vaginal ET is highly effective in treating symptomatic GSM, and tablets, rings, and creams have comparable efficacy (Lethaby, 2016). In addition, vaginal estrogen may help prevent recurrent urinary tract infections (UTIs) and overactive bladder symptoms in menopausal women. Systemic HT, in contrast, has been found to increase urinary incontinence incidence (The North American Menopause Society, 2013).

In the United States, two low-dose estrogen creams, a ring, a tablet, and inserts are available for vaginal use (Table 22-11). Creams are applied either digitally or with graduated, plastic applicators supplied with each tube. An advantage of the creams is that they can also be applied digitally to the vaginal vestibule. Less cream may be wasted with digital vulvovaginal application, which may extend the life of each tube. One disadvantage of creams is that some women find them messy.

The 3-month low-dose vaginal ring (Estring) releases 7.5 μg/d of E_2. For users, an advantage of the ring is the convenience of placement and removal only once every 3 months. However, some women are not comfortable inserting or removing the ring. Many women, as well as their partners, choose to leave

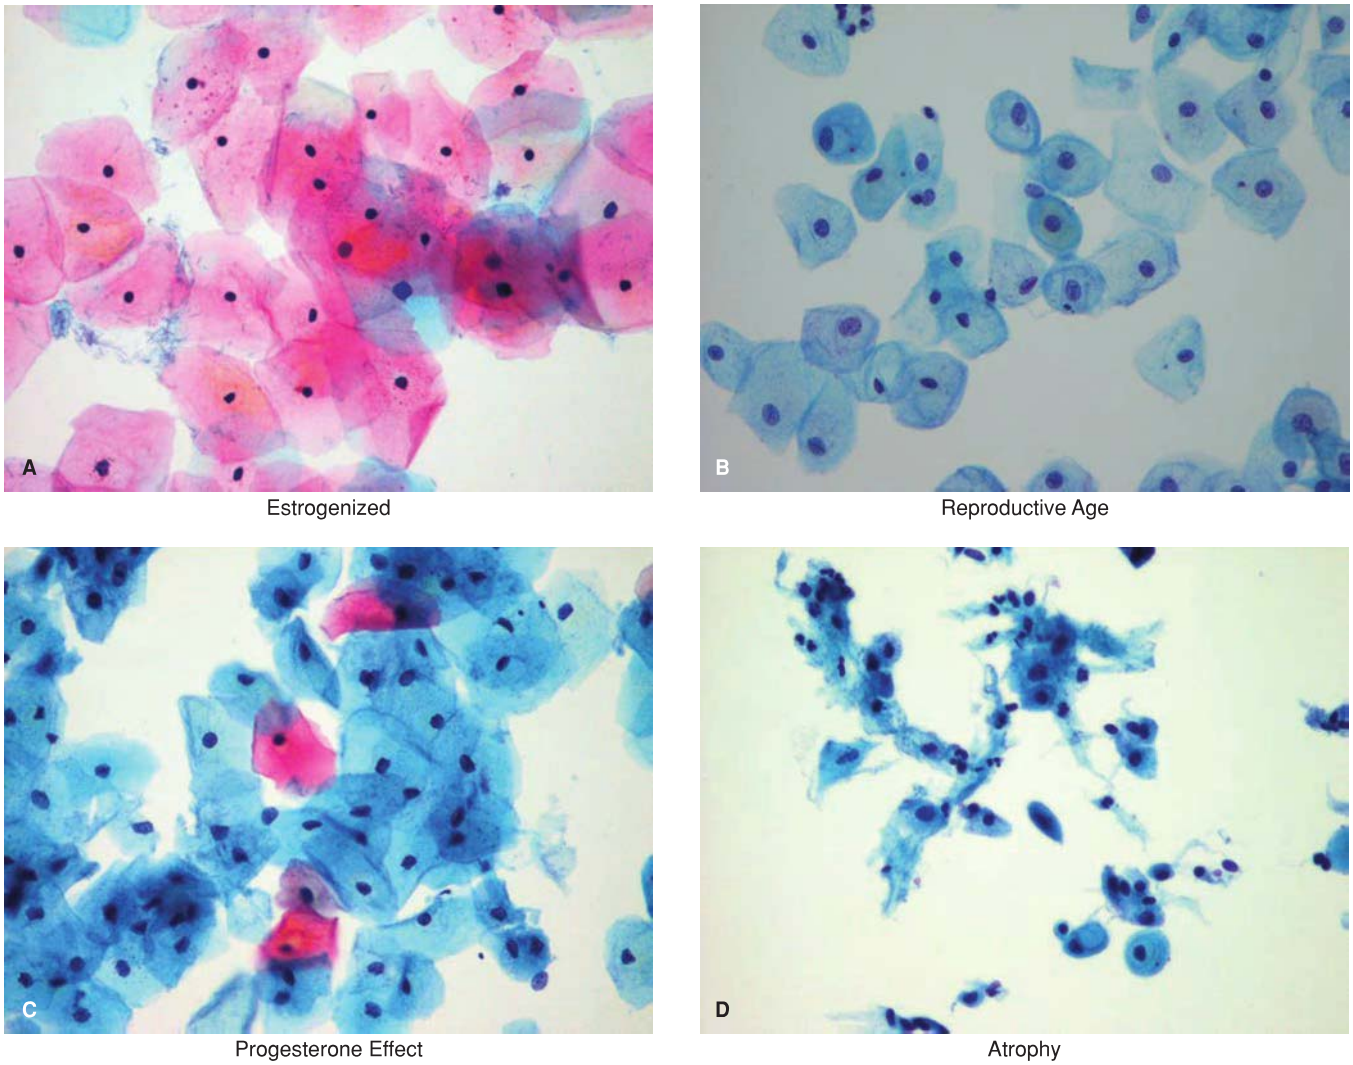

FIGURE 22-12 Cytologic specimens illustrate key points of the maturation index. This index provides insight into the cytohormonal status of the patient and is based on a count of parabasal, intermediate, and superficial (P:I:S) cells. Generally, a predominance of superficial or superficial and intermediate cells (**A** and **B**) is seen in reproductive-aged women. **C.** A predominance of intermediate cells is seen in the luteal phase, in pregnancy, with amenorrhea, and in newborns, premenarchal girls, and women in early menopausal transition. **D.** A predominance of parabasal cells is seen in menopausal patients with atrophy. (Reproduced with permission from Dr. Raheela Ashfaq.)

the ring in place during intercourse. If the ring is removed, it can be rinsed, avoiding detergent and hot water, and replaced as soon as possible.

Vaginal tablets (Vagifem or generic) employ a single-use plastic applicator to place one tablet nightly for two weeks and then twice weekly for maintenance therapy. Some women find the tablets less messy than creams. Another advantage is the thinner applicator compared with cream applicators.

In 2018, vaginal inserts (Imvexxy) were approved for treatment of moderate to severe dyspareunia associated with GSM. The inserts are placed digitally in the vagina without an applicator. The 4-μg insert is the lowest-dose vaginal E_2 formulation available (Constantine, 2017).

Guidance from the American College of Obstetricians and Gynecologists and the North American Menopause Society advise that low-dose vaginal ET may be used as long as needed. These groups additionally do not advise routine use of concomitant progestogen therapy for endometrial protection during long-term vaginal ET use. However, randomized trials assessing the endometrial safety of vaginal ET for longer than 1 year are not available. Endometrial evaluation is appropriate for women reporting vaginal spotting or bleeding during use of low-dose vaginal ET, as discussed in Chapter 8 (p. 183). In women without bleeding, routine endometrial surveillance is not recommended (American College of Obstetricians and Gynecologists, 2018c; The North American Menopause Society, 2013).

Current package labelling for low-dose vaginal ET, as for all systemic HT formulations, contains a black-box warning that mentions endometrial cancer, myocardial infarction, stroke, invasive breast cancer, pulmonary embolism, and dementia. This warning relates to safety concerns resulting from findings from clinical trials of systemic HT (p. 480). However, blood steroid levels are considerably less with low-dose vaginal ET formulations than with those observed during use of systemic ET. Moreover, clinical trials do not suggest an elevated risk of

TABLE 22-11. Selected Preparations for Genitourinary Symptoms of Menopause[a]

Preparation	Generic Name	Brand Name	Dose	Generic Available
Vaginal cream	Conjugated estrogens	Premarin	0.625 mg per 1 g cream (0.5 g twice wkly or 0.5 g/d for 3 wks, then 1 wk off. May titrate up to 2 g per application) (30-g tube)	No
	17β-Estradiol	Estrace	0.1 mg per 1 g cream (2–4 g/d for 1–2 wks, then 1–2 g/d for 1–2 wks, then 1–2 g 1 to 3 times wkly) (42.5-g tube)	Yes
Vaginal tablet	Estradiol	Vagifem	0.01-mg tablet (1 tablet/d for 2 wks, then 1 tablet twice weekly)	Yes
Vaginal ring	17β-Estradiol	Estring	2-mg ring delivers 7.5 μg daily (remains for 90 d)	No
Vaginal insert	Estradiol	Imvexxy	4-μg or 10-μg insert (1 insert/d for 2 wks, then 1 insert twice wkly)	No
	Prasterone	Intrarosa	6.5-mg insert daily	No
Oral tablet	Ospemifene	Osphena	60-mg tablet daily	No

[a]Most estrogen-containing products listed in Table 22-4 for the treatment of menopausal hot flashes are also approved for the treatment of vaginal dryness.

these adverse events. As a result, revised labeling that would better educate prescribers and women to these formulations' risk and benefits was advanced by several national organizations in women's health (Manson, 2014). However, the FDA rejected proposed changes, and the boxed warning continues on all systemic *and* vaginal estrogen-containing products.

Two large observational studies provide reassuring information regarding the safety of vaginal ET. In the WHI, more than 1500 women used vaginal ET for a median duration of 2 years. This practice did not raise associated risks for CHD, VTE, or endometrial, breast, or colorectal cancer (Crandall, 2018). Similarly, in the Nurse's Health Study, almost 900 women used vaginal ET for a mean duration of 3 years, and none of these same adverse-event rates was increased (Bhupathiraju, 2018).

Dehydroepiandrosterone or Prasterone

DHEA, also known as *prasterone*, is transformed by vaginal epithelial cells to various estrogens, including E_2, and into androgens, including testosterone (Labrie, 2018). In 2016, 6.5-mg prasterone tablets (Intrarosa) were approved for GSM treatment and are administered intravaginally nightly using a single-use plastic applicator. Data have not yet been published on its effects and safety in women with breast cancer or on aromatase inhibitors.

Ospemifene

The SERM ospemifene, provided in a 60-mg oral tablet (Osphena), also is FDA approved for treatment of dyspareunia associated with GSM. Use of an oral agent may appeal to women who prefer a nonvaginal route. A large 1-year clinical trial did not identify endometrial safety concerns (see Table 22-2). However, 2 percent of those receiving placebo reported hot flashes, whereas 7 percent of those taking ospemifene reported VMS (Simon, 2013). Other SERMs, including tamoxifen and raloxifene, can prompt VMS and raise VTE rates. The risk of similar effects with ospemifene is unknown (Simon, 2018).

Laser Therapy

GSM treatment of the vaginal wall with a carbon dioxide (CO_2) or yttrium-aluminum-garnet (YAG) laser is controversial. Minimally ablative fractional laser therapies are thought to activate cellular repair mechanisms. This in turn is suggested to enhance vascularity and collagen synthesis to thicken the vaginal wall. Histologic evaluation shows improvement similar to that from vaginal ET. Small studies have found that the fractional CO_2 laser significantly diminishes GSM symptoms after three vaginal laser treatments compared with baseline measures. YAG laser treatment has improved symptoms of GSM and stress urinary incontinence (Cruz, 2018; Rabley, 2018; Sokol, 2017). However, the FDA (2018) has not approved CO_2 laser therapy for GSM treatment and warns against its use without data from long-term, well-controlled studies. The American College of Obstetricians and Gynecologists (2016) echoes these concerns.

Dyspareunia

Sexual function declines with advancing menopause status, independently of age. The most frequently reported associated symptoms include low sexual desire, dyspareunia, and poor vaginal lubrication. Discussed in Chapters 4, 12, and 14, dyspareunia and sexual dysfunction are each rooted in a wide range of predisposing, precipitating, and maintaining factors, which may be biologic, psychologic, or sociocultural in origin (pp. 266, 312). In one study, 25 percent of postmenopausal women noted some degree of dyspareunia (Laumann, 1999). These same investigators found that painful intercourse

correlated with lack of libido, arousal disorder, and anorgasmia. Dennerstein (2005) prospectively evaluated 438 Australian women during 6 years of their MT. Menopause was significantly associated with dyspareunia and indirectly with sexual response. Levine and colleagues (2008) studied 1480 sexually active postmenopausal women and found that the prevalence of vulvovaginal atrophy and of female sexual dysfunction each approximated 55 percent. Women with sexual dysfunction were nearly four times more likely to have vulvovaginal atrophy than women without such dysfunction.

Estrogen deficiency diminishes vaginal lubrication, blood flow, and vasocongestion with sexual activity. These changes are coupled with the structural atrophy described earlier (p. 495). Reduced testosterone levels also are implicated in genital atrophy, but the relationship between testosterone and sexuality during MT remains obscure. Circulating testosterone levels decline gradually with age from the mid-reproductive years and have dropped by 50 percent by age 45. Paradoxically, studies have not demonstrated that sexual dysfunction is related to decreased androgen levels in MT (O'Neil, 2011).

Urogenital conditions such as prolapse or incontinence correlate strongly with sexual dysfunction (Barber, 2002; Salonia, 2004). Discussed in Chapter 23, patients with urinary incontinence may have pelvic-floor hypertonicity, which may cause pain on deep penetration due to pelvic support instability (p. 519). Hypertonic or dyssynergic pelvic-floor muscles, prevalent among women with urinary frequency, constipation, and vaginismus, are often associated with superficial pain and friction during intercourse (Handa, 2004). Discussed in Chapter 24, pelvic organ prolapse may contribute to dyspareunia (p. 541). In addition, prolapse-correcting surgery may cause dyspareunia by shortening or narrowing the vagina (Goldberg, 2001). Chronic pelvic pain or abdominal and vulvar scars or adhesions also may be contributors to sexual dysfunction as discussed in Chapter 12 (p. 257).

Urogynecologic Changes

As part of the GSM spectrum, urinary symptoms can include dysuria, urinary urgency, urethral eversion or prolapse, and recurrent UTIs (Portman, 2014: Trutnovsky, 2014). Discussed in Chapter 23, these can be associated with urethral and bladder mucosal thinning, and thus a trial of vaginal ET is reasonable (p. 513) (Cody, 2012; Eriksen, 1999; Rahn, 2014).

The association between declining estrogen levels and incontinence is more controversial. In support of a causal link, urethral shortening associated with menopausal atrophic changes may result in stress urinary incontinence. Waetjen and coworkers (2009) evaluated women in MT and found slightly higher stress and urgency incontinence rates. In addition, they identified that these urinary symptoms were robustly associated with worsening anxiety, high baseline BMI, weight gain, and new-onset diabetes. They concluded that clinicians and women should focus first on these modifiable risk factors. Sherburn and colleagues (2001) performed a cross-sectional study of women aged 45 to 55 years to determine if MT itself was associated with incontinence. The overall incidence was 35 percent, with no increase associated with menopause. Similarly, in a study of 382 women, stress and urgency urinary incontinence and the number of years following menopause were not significantly associated (Trutnovsky, 2014).

The effects of systemic HT on incontinence are conflicting. Bhatia and colleagues (1989) showed that systemic ET may improve or cure stress urinary incontinence in more than 50 percent of treated women, presumably by exerting a direct effect on urethral mucosa coaptation (Chap. 23, p. 528). However, two large trials noted that systemic HT users had a higher incidence of stress urinary incontinence (Hendrix, 2005; Jackson, 2006c).

With respect to vaginal ET, incontinence may be improved by enhancing periurethral and bladder-neck vascularity (Long, 2006). It also diminishes detrusor-contraction frequency and amplitude (Robinson, 2014). Thus, vaginal ET, when coupled with other strategies such as pelvic floor muscle training or pessary use, may have benefits. Evidence to support HT use for pelvic organ prolapse prevention is poor (Ismail 2010).

PSYCHOSOCIAL CHANGES

Libido Changes

Definitive data correlating the relationship between circulating hormone levels and libido are lacking. In the Massachusetts Women's Health Study II, sexual function in 200 women who underwent natural menopause was evaluated. None took HT, and all had sexual partners. Menopausal status significantly related to decreased sexual interest. However, after adjusting for physical and mental health, smoking, and marital satisfaction, the two were no longer associated. Indeed, many studies demonstrate that other factors besides menopause may account for libido changes (Gracia, 2007).

Some data, however, do show a link with menopause. A longitudinal study of women during MT until at least 1 year after the FMP demonstrated a significant decline in the rate of weekly coitus. Patients reported a significant drop in the number of sexual thoughts, sexual satisfactions, and vaginal lubrication after becoming menopausal (McCoy, 1985). In a study of 100 naturally menopausal women, both sexual desire and activity decreased compared with that during the premenopausal period. Women reported loss of libido, dyspareunia, and orgasmic dysfunction, and 86 percent reported no orgasms after menopause (Tungphaisal, 1991).

Estrogen can help GSM symptoms, as described on page 496. However, HT is not recommended as the sole treatment of other problems of sexual function, including diminished libido (North American Menopause Society, 2017).

Hypoactive Sexual Desire

Female sexual desire disorders include hypoactive sexual desire disorder (HSDD), female sexual arousal disorder, and orgasmic disorder/dysfunction. These may stem from neuroendocrine imbalance, ill health, interpersonal conflict, psychologic distress, and cultural or religious values. Discussed in Chapter 14 (p. 314), treatment options may include HT or other pharmacologic therapy combined with psychotherapy (Clayton, 2018; Kingsberg, 2017).

Androgen Therapy

Androgen therapy in women with HSDD is controversial. Androgen assays lack sensitivity and specificity, yielding uncertain associations between endogenous androgen concentrations and sexual function in women. Androgens can be converted in tissues, and there may be intracrine metabolism. No circulating androgen blood levels differentiate women with and without sexual dysfunction (Davis, 2019). Some studies document an association between androgen treatment and improved sexual desire, but large, quality trials with long-term surveillance are needed (Lobo, 2003; Pauls, 2005; Shifren, 2000). DHEA is an androgen precursor, and systematic reviews show no or only slightly improved sexual functioning in postmenopausal women taking this steroid systemically (Elraiyah, 2014; Scheffers, 2015). In contrast, vaginal DHEA is approved to treat GSM and improves sexual function in those women (p. 498).

Symptoms of androgen insufficiency include diminished sense of well-being, persistent fatigue, sexual function changes, and low serum free-testosterone levels. Women with these findings may be offered androgen therapy off label only, as no testosterone formulation is approved by the FDA for use in women. Therapy should be performed under close clinician supervision (Wierman, 2014).

Early effects of androgen therapy include acne and hirsutism. One study reported a 3-percent higher rate of acne in testosterone-therapy groups (Lobo, 2003). Long-term side effects such as male pattern baldness, voice deepening, and clitoral hypertrophy are infrequent within normal androgen levels. Androgen therapy may adversely affect the lipid profile, and long-term effects on cardiovascular and breast cancer risks are unknown (Braunstein, 2007; Davis, 2012, 2013).

A recent global consensus, following an extensive review and metaanalysis, concluded that testosterone therapy, *in doses that approximate physiologic testosterone concentrations for premenopausal women,* exert a beneficial effect on sexual function compared with placebo or comparator therapy. This was quantified as approximately one satisfying sexual event per month (Davis, 2019; Islam, 2019). Testosterone therapy enhances sexual desire, arousal, orgasmic function, pleasure, and sexual responsiveness and reduces sexual distress.

These doses of testosterone were noted to mildly promote acne and body and facial hair growth but not cause alopecia, clitoromegaly, or voice change. Although oral testosterone is associated with atherogenic lipid changes, non-oral, premenopausal-range doses are not associated with lipid changes, higher blood pressure, increased blood glucose or HbA_{1c} levels, or greater breast cancer risk with short-term use. The safety of physiologic doses of testosterone has been assessed for up to 2 years of use in healthy women without comorbidities. Based on expert opinion, the consensus group recommended that if an appropriate approved female testosterone preparation was not available, off-label prescribing of an approved male formulation would be reasonable. This was coupled with the provision that hormone concentrations are monitored and maintained in a physiologic female range. Supraphysiologic blood concentrations of testosterone provided by injections or pellets are not recommended.

Depression

Women carry a higher lifetime risk of developing depression than men. The risk of developing a major depressive disorder is 1.5 times higher in women than in men, particularly during reproductive years. A prior depressive episode, particularly if related to reproductive events, remains the strongest predictor of mood disorders or depression during midlife. VMS, anxiety, and other health-related issues can modulate depression risks (Soares, 2014).

Contemporary findings dispel myths that natural menopause itself is associated with depressed mood (Ballinger, 1990; Busch, 1994). However, a higher rate of depressive symptoms during MT is repeatedly observed in population-based studies. In the Penn Ovarian Aging Study, the risk was nearly three times higher in women in MT compared with premenopausal women. Moreover, women with no history of depression were two and a half times more likely to report depressed mood during MT than during the premenopausal period (Freeman, 2004). Other cohort studies report similar findings (Bromberger, 2011; Cohen, 2006; Dennerstein, 2004; Woods, 2008). Moreover, a high percentage of subjects suffer recurrent depression during MT (Freeman, 2007). Thus, a screen for depression is prudent for women in this transition, and tools are described in Chapters 1 (p. 18) and 14 (p. 303).

It has been suggested that significant and erratic hormonal fluctuations during early MT are in part responsible (Soares, 2005). Ballinger and colleagues (1990) showed that increased stress hormone levels and probably stress-related symptoms are physiologically linked with high estrogen levels. They also reported that women with abnormal psychometric test scores early after menopause had higher E_2 levels than women with lower scores. Spinelli and associates (2005) showed that estrogen levels correlate with menopausal symptom intensity. Moreover, in a randomized menopause-treatment study, standard CEE doses (0.625 mg/d) significantly improved sleep but also were associated with an estrogen-related increase in inward-directed hostility (Schiff, 1980).

Importantly, MT is a complex sociocultural event, and psychosocial factors may contribute to mood and cognitive symptoms. Women entering MT may face emotional stress from onset of a major illness, caring for an adolescent or aging parent, divorce or widowhood, and career change or retirement. Lock (1991) suggests that part of the stress reported by Western women is clearly culture-specific. Western culture emphasizes beauty and youth, and as women grow older, some suffer from a perceived loss of status, function, and control (LeBoeuf, 1996). For some women, the approach of menopause may also be perceived as a significant loss, both to women who have accepted childbearing and rearing as their major life roles and to those who are childless, perhaps not by choice. For these reasons, impending menopause may be perceived as a time of loss, when depression and other psychological disorders may develop (Avis, 2000). New guidelines recognize a greater risk of depression during perimenopause, and those with a prior depressive episode carry a higher risk. Women often present with classic depression symptoms and coexistent menopausal hot flashes, sleep disturbances, and psychosocial changes, making the diagnosis more challenging (Maki, 2018).

Discussed in Chapter 14 (p. 309), antidepressant medications combined with psychotherapy and counseling are principal therapeutic interventions for women with depression. HT is not considered treatment for depression. However, lesser mood symptoms may be improved concurrently with hot flash frequency and disrupted sleep (Soares, 2001; Zweifel, 1997). Fewer data are available for EPT than ET (Maki, 2018). For those with bothersome VMS and disordered mood during MT, a trial of HT may be elected. Specifically, consideration may be given to those who fail to respond to a conventional first-line intervention, those who refuse to take psychotropic agents, or those who will begin HT for other acute menopausal symptoms and who could delay antidepressant therapy until determining whether HT is sufficient.

CENTRAL NERVOUS SYSTEM

Sleep Dysfunction and Fatigue

Sleep quality declines with age, but MT appears to contribute. As women traverse MT, the self-reported poor-sleep rate rises, and the rate was 38 percent in the 12,603 women participating in the SWAN study (Hall, 2009). As with most menopausal symptoms, severity and prevalence both seem to peak during late MT, when women experience prolonged amenorrhea. Women may wake several times during the night and may be drenched in sweat. In one study, late-reproductive-aged women with a greater frequency of hot flashes were more likely to report poor sleep than were women with fewer VMS events (Hollander, 2001). In one study, 255 women were premenopausal at cohort enrollment, underwent natural menopause, and were followed for 16 years. The most important predictor of moderate or severe poor sleep during MT was the premenopausal sleep status. Hot flashes contributed to poor sleep regardless of baseline sleep status (Freeman, 2015). Nocturnal hot flashes are felt to be an important component, particularly in women with severe sleep difficulties (Baker, 2018).

Even women with mild VMS may experience insomnia (Erlik, 1982; Woodward, 1994). As women age, they are more likely to experience lighter sleep and are awakened more easily by pain, sound, or bodily urges. Health issues and other chronic conditions experienced by women or by their spouse or bedmate are likely to further disrupt sleep. Arthritis, carpal tunnel syndrome, chronic lung disease, heartburn, and certain medications that are known to disrupt sleep may dramatically lower the quality and quantity of restful sleep. Nocturia, urinary frequency, and urgency, all of which are more common in menopausal women, are other notable factors.

Sleep disordered breathing, which includes various degrees of pharyngeal obstruction, is common in menopausal women and their mates. Loud snoring can follow partial upper airway obstruction that ranges in severity from upper airway resistance to *obstructive sleep apnea (OSA)* (Gislason, 1993). OSA can have associated health consequences, and one screening method is found in Chapter 39 (p. 839). In women, sleep disordered breathing is often associated with higher BMI and declining estrogen and progesterone levels.

Disturbed sleep can lead to fatigue, irritability, depressive symptoms, cognitive dysfunction, and impaired daily functioning. Common sense education components may include control of sleep timing and duration, attempts to improve the bedroom environment, or relaxation or biofeedback techniques. Importantly, although fatigue may stem from night sweats and poor sleep, other common potential etiologies, such as anemia or thyroid disease, among others, also are considered. In all these examples, treatment of underlying health conditions is the main focus to improve patient sleep. At times, short-term use of pharmacologic sleep aids is indicated, and these are listed in Table 1-16 (p. 19). HT can improve sleep disturbances and sleep quality, often along with improvement in hot flash frequency (Cintron, 2017).

Cognitive Dysfunction

Memory declines with advancing age. Although no direct effect of lowered estrogen levels on memory and cognition has been determined, many investigators suspect a relationship between the two. Cognitive functioning was assessed in a cohort study of reproductive-aged and postmenopausal women not using HT. In postmenopausal patients, cognitive performance declined with advancing age. This was not the case for reproductive-aged women. Premenopausal women in their 40s were less likely to exhibit cognitive decline compared with postmenopausal patients in the same decade of life. These researchers concluded that deterioration of some forms of cognitive function is accelerated after menopause (Halbreich, 1995).

In another study, 643 healthy postmenopausal women not using HT were grouped as early (<6 years after menopause) and late (>10 years after menopause) and underwent a comprehensive neuropsychologic battery (Henderson, 2013). Concurrently, serum hormone levels were measured. Cognitive outcomes included verbal memory, executive function, and global cognition scores. Endogenous sex steroid levels were unassociated with composite scores, but SHBG levels were positively associated with verbal memory. Results for early and late groups did not differ significantly, although progesterone concentrations were significantly positively associated with verbal memory and global cognition in early group women. Hormone levels were not significantly related to mood.

Factors accelerating cerebral degenerative changes represent potentially modifiable risks for cognitive decline (Kuller, 2003; Meyer, 1999). Risk factors for decreased cerebral perfusion and thinning of gray and white matter densities include prior transient ischemic attacks (TIAs), hyperlipidemia, hypertension, smoking, excess alcohol consumption, and male gender, which would imply lack of estrogen. Investigators encourage interventions to modify many of these risks.

Alzheimer Senile Dementia

Dementia is defined as a progressive decline in intellectual and cognitive function. Its causes can be categorized into three broad groups: (1) cases in which the brain is the target of a systemic illness; (2) primary structural causes such as tumor; and (3) primary degenerative diseases of the nervous system, such as senile dementia of the Alzheimer type (SDAT). It is estimated that up to 50 percent of women aged 85 years or older may suffer from senile dementia or SDAT. Early signs may be subtle, and testing strategies are found in Chapter 1 (p. 18).

The role of estrogen in dementia prevention is controversial. Several epidemiologic studies suggested that HT prevents SDAT development. Moreover, metaanalyses of observational studies show that HT is associated with a lower risk of dementia but does not improve established disease (Yaffe, 1998; Zandi, 2002). However, data from a large randomized trial found no preventive role. Women enrolled in the Women's Health Initiative Memory Study (WHIMS), an ancillary study of the WHI, had higher rates of dementia compared with those given placebo (Shumaker, 2003, 2004). Notably, this increased risk was statistically significant only in the group of women >75 years. This observation is concerning for its long-term implications for HT in older postmenopausal women. It is unclear whether, similar to CHD, a critical window and timing hypotheses alter HT effects on SDAT development. Unfortunately, these mixed findings leave unanswered questions regarding HT's efficacy in preventing dementia in postmenopausal women. Currently, HT is not recommended for this indication.

OTHER PHYSIOLOGIC CHANGES

Cardiovascular Changes

In women older than 50 years, atherosclerotic cardiovascular disease (CVD) remains the leading cause of death. Before menopause, women have a much lower risk for cardiovascular events compared with men their same age. Reasons for protection from CVD in premenopausal women are complex, but a significant contribution is assigned to greater high-density lipoprotein (HDL) levels in younger women, which is an effect of estrogen. However, after menopause, this benefit disappears over time such that a 70-year-old woman begins to have a CVD risk identical to that of a man of comparable age (Matthews, 1989). The risk of CVD increases dramatically for women as they enter menopause and as estrogen levels decline (Matthews, 1994; van Beresteijn, 1993). This becomes vitally important for women in MT, when preventive measures can significantly improve both life quality and quantity. The value of HT to alter CVD risks was described earlier on page 480. Preventive measures are outlined in Chapter 1 (p. 15).

Weight Gain and Fat Distribution

Weight gain is a common complaint during MT (Karvonen, 2016). On average, women gain 1.5 pounds per year during the fifth and sixth decades independent of initial body size, race, or ethnicity (Sternfeld, 2004). With aging, a woman's metabolism slows, reducing her caloric requirements. If eating and exercise habits are not altered, weight is gained (Matthews, 2001). Specifically, Espeland and associates (1997) characterized the weight and fat distribution of 875 women in the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial and correlated the effects of lifestyle, clinical, and demographic factors. Women aged 45 to 54 years had significantly greater increases in weight and in hip circumference than those aged 55 to 65 years. These investigators reported that overall baseline physical activity and baseline leisure and work activities were strongly related to weight gain in the PEPI cohort. Women who reported more activity gained less weight than less active women.

Weight gain during this period is associated with fat deposition in the abdomen (central or android pattern) and increased amounts of visceral fat (Kim, 2014). In addition, older adults have higher percentages of body fat than younger adults at any age due to muscle mass loss with aging (Baumgartner, 1995).

The etiology of these changes are multifactorial, and age-related metabolism slowing, declining estrogen levels, mood disorders, sleep disturbances, and often less strenuous physical activity can be contributory (Patel, 2006; Shifren, 2014). Others include genetic factors, neuropeptides, and adrenergic nervous system activity (Milewicz, 1996; Zaitlen, 2013). Many women believe that ET at menopause causes weight gain. However, results from clinical trials and epidemiologic studies indicate that the effect of HT on body weight and girth, if any, is to slightly blunt the rate of age-related increases.

Central obesity is associated with greater insulin resistance and diabetes risks, elevated atherogenic lipid levels, hypertension, cardiovascular disease, and mortality (Dallman, 2004; Manson, 1995; Wing, 1991). Weight gain during MT and after menopause raises health risks that include cancer, osteoarthritis, mood disorders, more frequent or severe hot flashes, and sexual dysfunction (Lauby-Secretan 2016; Shifren, 2014; Thurston, 2009).

Lifestyle interventions to minimize fat mass gains and central fat distribution during MT predominantly include exercise and healthy nutrition. These are discussed fully in Chapter 1 (p. 12). Barriers to these positive changes included untreated VMS, inadequate exercise, sleep disturbances, and untreated or inadequately treated mood disorders (Grindler, 2015). HT improves menopausal symptoms and sleep disturbances. It also improves body fat distribution but is not recommended as a treatment for central obesity. Preclinical and limited clinical studies find that skeletal muscle has estrogen receptors. Unfortunately, HT does not prevent age-related loss of lean body mass (sarcopenia) (Javed, 2019).

Breast Changes

The breast undergoes change during MT mainly because of hormonal withdrawal. In premenopausal women, estrogen and progesterone exert proliferative effects on ductal and glandular structures, respectively. At menopause, withdrawal of these hormones leads to a relative reduction in breast proliferation. A significant reduction in volume and tissue density is seen during mammography as these areas become replaced with adipose tissue. Screening for breast cancer, including mammography, is appropriate for women using HT. Shared decision-making is used to determine screening onset and frequency. Breast imaging recommendations are fully discussed in Chapter 13 (p. 293).

The role of tissue estrogen levels in breast carcinogenesis and the levels of metabolites in healthy breast tissue remains poorly understood (Yaghjyan, 2011). The effects of HT on breast cancer risk continue to be complex. This is especially so considering the different breast effects seen with differing HT regimens and differing initiation times relative to menopause onset and may be related to underlying breast cancer risk.

Dermatologic Changes

As people age, their skin loses elasticity, collagen fibers, vascularity, and moisture. Approximately 30 percent of collagen may

be lost within the first 5 years after menopause (Brincat, 2005; Calleja-Agius, 2009). As a result, the skin lies more loosely, and lines appear where the facial muscles attach to the skin's undersurface. Skin aging results from synergistic effects of intrinsic aging and photo-aging from sun exposure or other environmental insults (Guinot, 2005). Cosmetic changes include hyperpigmentation (age spots), wrinkling, thinning, dryness, and decreased elasticity. More seriously, wound healing can be compromised, and the susceptibility to some skin cancers is increased (Thornton, 2013).

Skin is a hormonally sensitive structure and contains both estrogen and androgen receptors (Hasselquist, 1980). Hormonal dermal changes include reduced thickness of the skin with lower collagen content, diminished sebaceous gland secretion, loss of elasticity, and decreased blood supply (Wines, 2001). However, separating hormonal deficiency from chronologic skin aging and age-related environmental insults such as smoking or photo-aging is difficult.

People with thin, dry, fair skin experience signs of facial aging earlier. Overexposure to sunlight and excessive use of tobacco and alcohol accelerate skin aging. Thus, prevention of skin aging includes protection from ultraviolet light, avoidance of tobacco, and limiting alcohol intake.

Estrogen therapy may modulate some skin changes, as its use is associated with increased epidermal and dermal thickness, greater collagen and elastin content, improved skin moisture, and fewer wrinkles (Emmerson, 2012). The predominant evidence for an estrogen effect on skin derives from observational studies using various estrogen preparations with or without cyclic progestogens. Thus, clearly assigning the effects to estrogen, progestogen, or both is challenging. Results from randomized trials show improvement in certain skin parameters, but these were inconsistent among the trials (Maheux, 1994; Sator, 2007; Sauerbronn, 2000). In the largest trial, low-dose HT (1 mg norethindrone acetate with either 5 μg or 10 μg of ethinyl estradiol) did not significantly alter age-related facial skin changes in 320 women who averaged 5 years from menopause and received treatment rather than placebo for 48 weeks (Phillips, 2008). Benefits may be greater if HT is initiated closer to menopause and prior to a significant loss of collagen. Currently, evidence is insufficient to recommend systemic HT to improve age-related skin characteristics. In small trials, topical estrogen applied to the face led to a thicker epidermis and fewer fine wrinkles (Creidi, 1994; Patriarca, 2007).

After menopause, women may experience hair loss or greater hair density. Recognized conditions include female pattern hair loss (androgenetic) and telogen effluvium. Although the characteristic low estrogen-to-androgen ratio could affect hair changes in genetically susceptible individuals, no role has been identified for HT to prevent hair loss. Antiandrogen treatments increase hair density for some women (Riedel-Baima, 2008).

Dental Changes

Dental problems also may develop as estrogen levels wane in late MT. Hormones influence oral health, and estrogen receptors are observed in the oral mucosa, gingiva, and salivary glands (Grover, 2014). The buccal epithelium atrophies due to estrogen deprivation and results in diminished saliva and sensation. Dysgeusia (bad taste in the mouth), higher incidence of cavities, and tooth loss also may occur (Krall, 1994). Oral alveolar bone loss is strongly positively correlated with osteoporosis and can lead to tooth loss. Even in women without osteoporosis, vertebral BMD correlates positively with the number of teeth. In turn, the beneficial effect of estrogen on skeletal bone mass is also manifested in oral bone.

DEFINITIONS

Urinary incontinence is defined as involuntary leakage of urine. This contrasts with urine that leaks from extraurethral sources, such as fistulas or lower urinary tract congenital malformations. Although incontinence is categorized into several forms, this chapter focuses on the evaluation and management of stress and urgency urinary incontinence. *Stress urinary incontinence* (SUI) is the involuntary leakage of urine with increases in intraabdominal pressure. *Urgency urinary incontinence* is the involuntary leakage accompanied or immediately preceded by a perceived strong imminent need to void. A related condition, *overactive bladder*, describes urinary urgency with or without incontinence and usually with greater daytime urinary frequency and nocturia (Abrams, 2009).

According to International Continence Society guidelines, urinary incontinence is a symptom, a sign, and a condition (Abrams, 2002). For example, with SUI, a patient may complain of involuntary urine leakage with exercise or laughing. Concurrent with these symptoms, involuntary leakage from the urethra synchronous with cough or Valsalva may be observed during examination by a provider. And as a condition, SUI is objectively demonstrated during urodynamic testing if involuntary leakage of urine accompanies increased abdominal pressure and absence of detrusor muscle contraction. Under these circumstances, when the symptom or sign of SUI is confirmed with objective testing, the term *urodynamic stress incontinence* is preferred.

With urgency urinary incontinence, women have difficulty postponing urination urges and generally must promptly empty their bladder on cue and without delay. Common triggers are hand washing, running water, or exposure to cold. Urgency urinary incontinence is sometimes objectively demonstrated during urodynamic testing to correspond temporally with spontaneous detrusor muscle contractions—a condition termed *detrusor overactivity*. When both stress and urgency symptoms are present, it is called *mixed urinary incontinence*.

EPIDEMIOLOGY

In Western societies, epidemiologic studies indicate a prevalence of urinary incontinence of 25 to 51 percent and even higher among nursing home patients (Buckley, 2010; Markland, 2011). This wide range is attributed to variations in research methodologies, population characteristics, and definitions of incontinence. As part of the 2005 to 2006 National Health and Nutrition Examination Survey (NHANES), urinary incontinence characterized by participants as moderate to severe leakage was identified in 16 percent (Nygaard, 2008). A subsequent review of NHANES confirmed a similar rate of 17 percent (Wu, 2014). Among ambulatory women with urinary incontinence, SUI represents 29 to 75 percent of cases. Urgency urinary incontinence accounts for up to 33 percent, whereas the remainder is attributable to mixed forms (Hunskaar, 2000). However, current available data are limited by the fact that most women do not seek medical attention for this condition (Hunskaar, 2000). It is estimated that only one in four women will seek medical advice for incontinence, due to embarrassment, limited health-care access, or poor screening by health-care providers (Hannestad 2002; Minassian, 2012).

Urinary incontinence can significantly impair quality of life and lead to disrupted social relationships, embarrassment and frustration, and hospitalizations due to skin breakdown and urinary tract infection (UTI). As up to one third of incontinent women have urinary leakage during sexual activity, incontinence—or fear of incontinence—during intercourse may contribute to sexual dysfunction (Gray, 2018; Serati, 2009). Older women with incontinence are 2.5 times more likely to be admitted to a nursing home than continent women (Langa, 2002). Moreover, population projections from the U.S. Census Bureau forecast that the number of American women with urinary incontinence will increase 55 percent from 18.3 million to 28.4 million between 2010 and 2050 (Wu, 2009).

RISKS

Age

The prevalence and severity of incontinence appears to rise gradually with age during young adult life. Data from the 2005 to 2006 NHANES demonstrated an incontinence prevalence of 7 percent in those aged 20 to 40 years, 17 percent for ages 40 to 60, 23 percent for ages 60 to 80, and 32 percent for those older than 80 (Nygaard, 2008).

Redistribution

Chronically increased abdominal pressure
Chronic cough
Constipation
Occupational lifting

Incontinence should not be viewed as a normal consequence of aging (Table 23-1). However, several physiologic age-related changes in the lower urinary tract may predispose to incontinence, overactive bladder, or other voiding difficulties. First, the prevalence of involuntary detrusor contractions increases with age, and detrusor overactivity is found in 21 percent of healthy, continent community-dwelling elderly (Resnick, 1995). Both total bladder capacity and the ability to postpone voiding decreases, and these declines may lead to urinary frequency. In addition, urinary flow rates are reduced in older women and are likely due to an age-associated decrease in detrusor contractility (Resnick, 1984). In women, postmenopausal drops in estrogen levels result in atrophy of the urethral mucosal seal, loss of compliance, and bladder irritation, which may predispose to both SUI and urgency urinary incontinence. Finally, renal filtration rate and diurnal levels of antidiuretic hormone and atrial natriuretic factor change with age. These shift the diurnal-predominant pattern of fluid excretion toward one with greater urine excretion later in the day (Kirkland, 1983).

Childbirth

Childbirth and pregnancy also play a role, and urinary incontinence prevalence is higher in parous women compared with nulliparas. The effects of childbirth may result from direct injury to pelvic muscles and connective tissue attachments. In addition, nerve damage from trauma or stretch injury can lead to pelvic muscle dysfunction. Specifically, rates of prolonged pudendal nerve latency after delivery are higher in women with incontinence compared with asymptomatic puerpera (Snooks, 1986).

Of potential obstetric factors, one large study identified that fetal birthweight >4000 g elevates the risk of all urinary incontinence types (Rortveit, 2003b). These authors also noted that cesarean delivery may offer a short-term protective effect from urinary incontinence. The adjusted odds ratio for any incontinence associated with vaginal delivery compared with that with cesarean delivery was 1.7 (Rortveit, 2003a). However, the protective effect of cesarean delivery on incontinence may dissipate after additional deliveries, declines with age, and is no longer present in older women (Nygaard, 2006).

Other Factors

Race may influence incontinence rates, and white women are believed to have higher SUI rates than women of other races. In contrast, urgency urinary incontinence is believed to be more prevalent among African-American women. Most reports are not population based and thus are not the best estimate of true racial differences. However, data from the Nurses' Health Study cohorts, which included more than 76,000 women, did support these racial differences (Townsend, 2010). Whether these differences are biologic, related to health-care access, or affected by cultural expectations and symptom tolerance thresholds is unclear.

Body mass index (BMI) is a significant and independent risk factor, and the prevalence of both urgency urinary incontinence and SUI rises proportionally with BMI. (Hannestad, 2003). Compared to nonobese women, obese women have an approximately threefold greater likelihood of urinary incontinence (Al-Mukhtar, 2017; Lawrence, 2007). Theoretically, the increase in intraabdominal pressure that coincides with a higher BMI results in a higher intravesical pressure. This greater pressure overcomes urethral closing pressure and leads to incontinence (Bai, 2002). Encouragingly, weight loss is considered a first-line option, and the prevalence of urinary incontinence significantly declines following weight loss achieved by behavior modification or with bariatric surgery (Burgio, 2007; Deitel, 1988; Dumoulin, 2016; Subak, 2009). Even losses of 5 to 10 percent of body weight are sufficient for significant improvement in urinary incontinence (Wing, 2010).

Menopause may have a relationship with incontinence, but studies have inconsistently demonstrated an increase in urinary dysfunction rates (Bump, 1998). In those with symptoms, separating aging changes from hypoestrogenism effects is difficult. First, high-affinity estrogen receptors are found in the urethra, pubococcygeal muscle, and bladder trigone but are infrequently found elsewhere in the bladder (Iosif, 1981). Hypoestrogenic-related collagen changes and reductions in urethral vascularity and skeletal muscle volume are factors. They are thought collectively to contribute to impaired urethral function by lowering the resting urethral pressure (Carlile, 1988). Moreover, estrogen deficiency with resulting urogenital atrophy is believed to be responsible in part for urinary sensory symptoms following menopause (Raz, 1993). Despite this evidence, it is less clear whether estrogen therapy is useful in the treatment or prevention of incontinence. Curiously, systemic estrogen replacement, compared with placebo, appears to worsen incontinence, but topical vaginal estrogen application *may improve* it (Cody, 2012; Fantl, 1994, 1996; Rahn, 2014, 2015).

Family history may alter incontinence risks, and the urinary incontinence rates—particularly for urgency urinary incontinence—may be higher in the daughters and sisters of incontinent women. In one large survey, daughters of incontinent women had an increased relative risk of 1.3 and an absolute risk of 23 percent of having urinary incontinence. Younger sisters of incontinent women also had a greater likelihood of having any urinary incontinence (Hannestad, 2004).

Chronic obstructive pulmonary disease in women older than 60 years significantly elevates urinary incontinence risks (Brown, 1996; Diokno, 1990). Similarly, cigarette smoking is identified as an independent risk factor for urinary incontinence. Both current

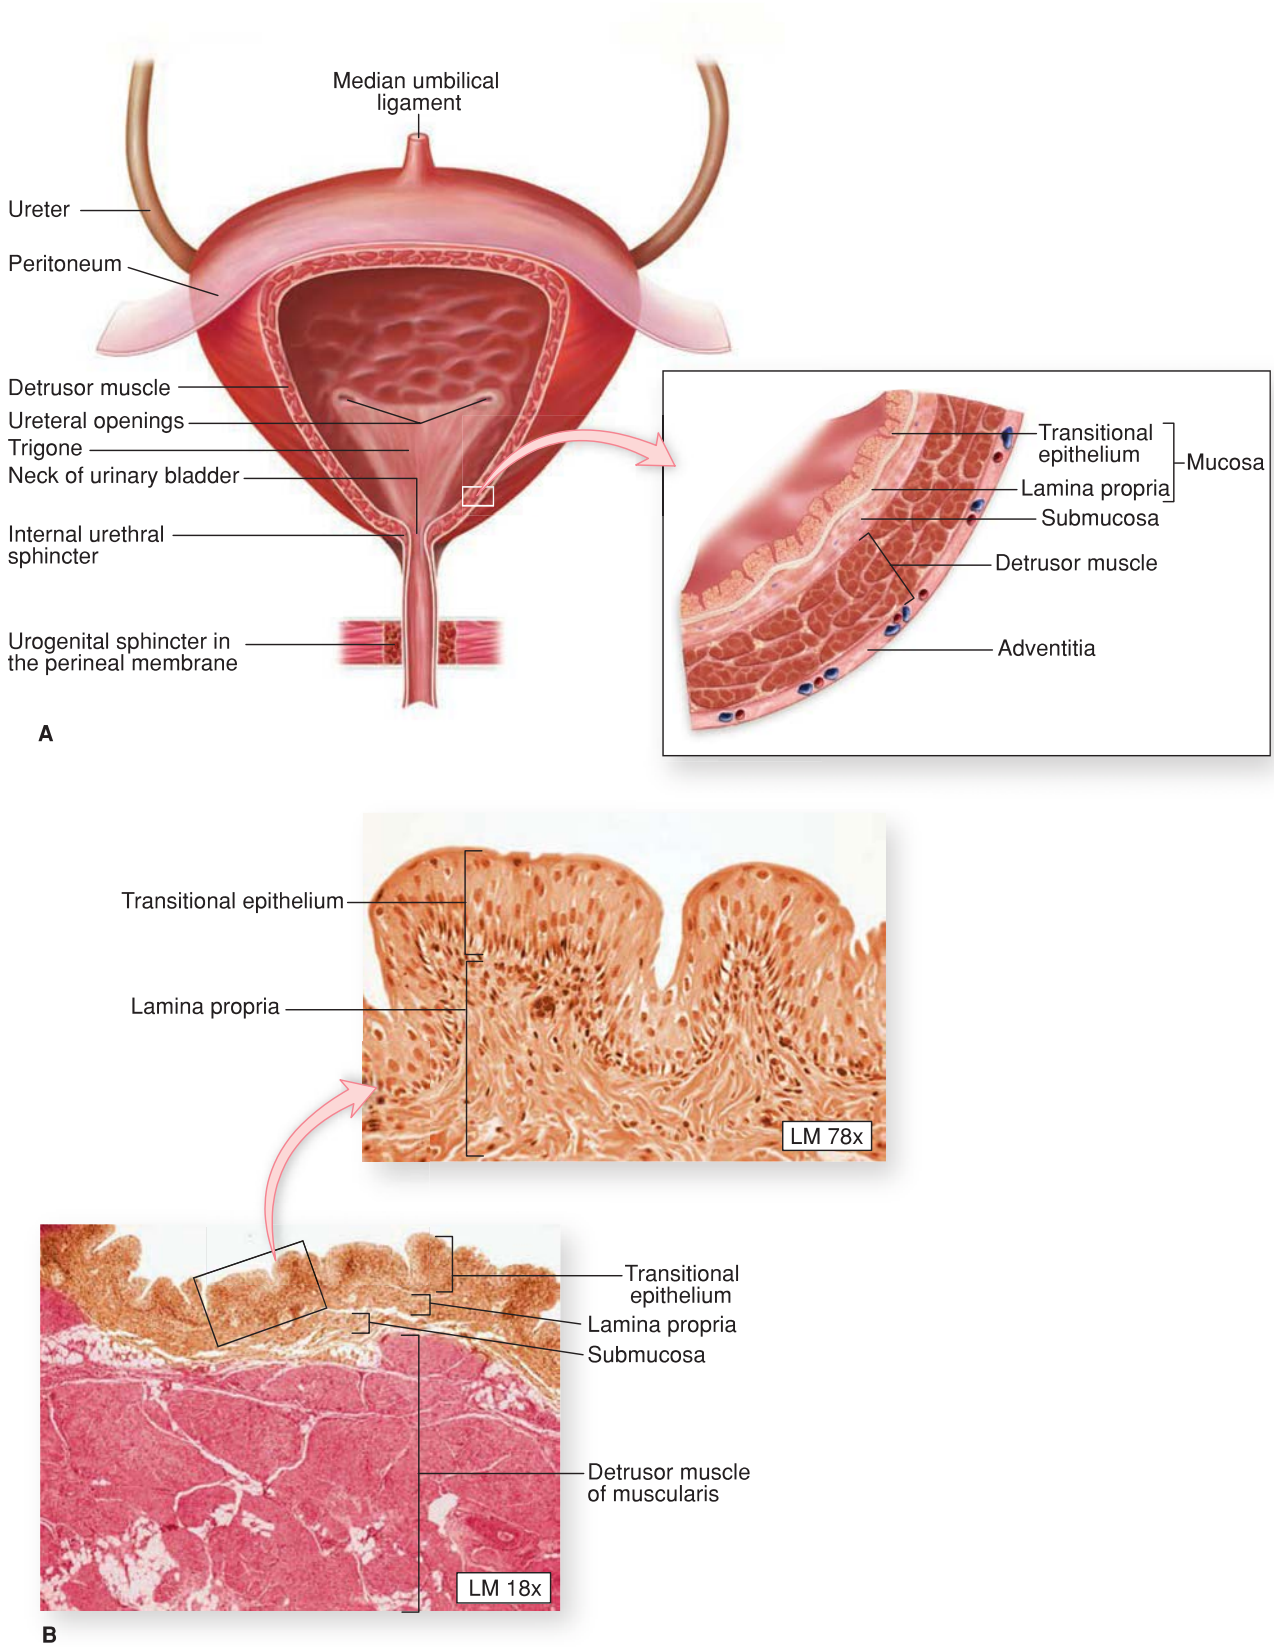

FIGURE 23-1 Bladder anatomy. **A.** Anteroposterior view of bladder anatomy. Inset: The bladder wall contains mucosal, submucosal, muscular, and adventitial layers. **B.** Photomicrograph of the bladder wall. (Reproduced with permission from McKinley, 2006.)

and former smokers have a two- to threefold risk of incontinence compared with nonsmokers (Brown, 1996; Bump, 1992; Diokno, 1990). In one study, current and former smoking was associated with incontinence, but only for those who smoked more than 20 cigarettes daily. Severe incontinence was weakly associated with smoking regardless of cigarette number (Hannestad, 2003). Theoretically, persistently elevated intraabdominal pressures are generated from a smoker's chronic cough, and collagen synthesis is diminished by smoking's antiestrogenic effects.

Hysterectomy does not appear to raise urinary incontinence rates. Studies that include pre- and postoperative urodynamic testing reveal clinically insignificant changes in bladder function. Moreover, evidence does not support avoidance of clinically indicated hysterectomy or the selection of supracervical hysterectomy as measures to prevent urinary incontinence (Vervest, 1989; Wake, 1980).

PATHOPHYSIOLOGY

Continence

The bladder has the capacity to accommodate large increases in volume with minimal or no increases in intravesical pressure. The ability to store urine coupled with convenient and socially acceptable voluntary emptying is *continence*. Continence requires the complex coordination of multiple components that include: muscle contraction and relaxation, appropriate connective tissue support, and integrated innervation and communication between these structures. Simplistically, during filling, urethral contraction is coordinated with bladder relaxation and urine is stored. During voiding, the urethra relaxes and the bladder contracts. These mechanisms can be challenged by uninhibited detrusor contractions, marked increases in intraabdominal pressure, and degradation or dysfunction of the various anatomic components of the continence mechanism.

Bladder Filling

Bladder Anatomy

The bladder wall is multilayered and contains mucosal, submucosal, muscular, and adventitial layers (Fig. 23-1). The bladder mucosa is composed of a transitional cell epithelium, supported by a lamina propria. With small bladder volumes, the mucosa appears as convoluted folds. However, with bladder filling, it is stretched and thinned. The bladder epithelium, termed uroepithelium, is made up of distinct cell layers. The most superficial is the umbrella cell layer, and its impermeability is thought to provide the primary urine-plasma barrier. Covering the *uroepithelium* is a glycosaminoglycan (GAG) layer. This GAG layer may prohibit bacterial adherence and prevents urothelial damage by acting as a protective barrier. Specifically, theories suggest that this carbohydrate polymer layer may be defective in patients with interstitial cystitis (Chap. 12, p. 267).

The muscular layer, termed the detrusor muscle, is composed of three smooth-muscle layers arranged in a plexiform fashion. This unique arrangement allows for rapid multidimensional expansion during bladder filling and is a key component to the bladder's ability to accommodate large volumes.

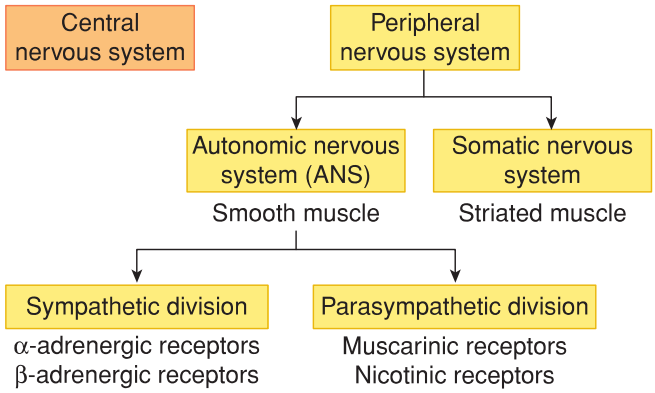

FIGURE 23-2 Divisions of the human nervous system. The peripheral nervous system includes: (1) the somatic nervous system, which mediates voluntary movements through its actions on striated muscle and (2) the autonomic nervous system, which controls involuntary motion through its actions on smooth muscle. The autonomic nervous system is further divided into the sympathetic division, which acts through epinephrine and norepinephrine binding to adrenergic receptors and (2) the parasympathetic division, which acts through acetylcholine binding to muscarinic or nicotinic receptors.

Innervation

Normal function of the lower urinary tract requires integration of peripheral and central nervous systems. The peripheral nervous system contains somatic and autonomic divisions (Fig. 23-2). Of these, the somatic component innervates striated muscle, whereas the autonomic division innervates smooth muscle.

The autonomic nervous system controls involuntary action and is categorized into sympathetic and parasympathetic divisions. The sympathetic system mediates its end-organ effects through epinephrine or norepinephrine acting on α- or β-adrenergic receptors (Fig. 23-3). The parasympathetic division acts through

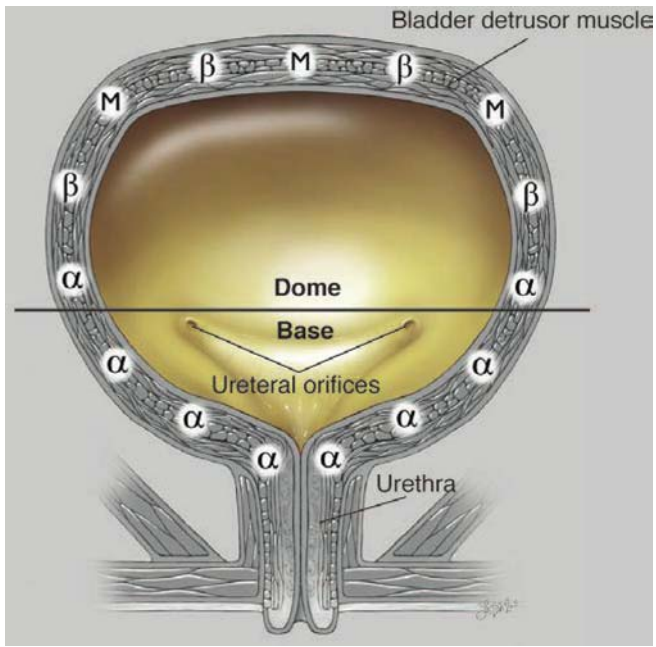

FIGURE 23-3 The bladder dome is rich in parasympathetic muscarinic receptors (M) and sympathetic β-adrenergic receptors (β). The bladder neck contains a greater density of sympathetic α-adrenergic receptors (α). (Reproduced with permission from Lindsay Oksenberg.)

acetylcholine binding to muscarinic or nicotinic receptors. In the pelvis, autonomic fibers that supply the pelvic viscera course in the superior and inferior hypogastric plexi (Fig. 23-4).

The somatic nervous system controls voluntary movement, and the portion of this system that is most relevant to lower urinary tract function originates from the Onuf somatic nucleus. This nucleus is located in the ventral horn gray matter of spinal levels S2–S4 and contains the neurons that innervate the striated urogenital sphincter complex, described next. Nerves involved with that connection include branches of the pudendal and pelvic nerves.

Urogenital Sphincter

As the bladder fills, synchronized contraction of the urogenital sphincter is integral to continence. Composed of striated muscle, this sphincter complex includes: (1) the *sphincter urethrae*, (2) the *urethrovaginal sphincter*, and (3) the *compressor urethrae*. The sphincter urethrae wraps circumferentially around the urethra. In comparison, the urethrovaginal sphincter and the compressor urethrae arch ventrally over the urethra and insert into the fibromuscular tissue of the anterior vaginal wall (Fig. 23-5).

These three muscles function as a single unit and contract to close the urethra. Contraction of these muscles circumferentially constricts the cephalad two thirds of the urethra and laterally compresses the distal one third. The sphincter urethrae is predominantly composed of slow-twitch fibers and remains tonically contracted, contributing substantially to continence at rest. In contrast, the urethrovaginal sphincter and the compressor urethrae are comprised of fast-twitch muscle fibers, which allow brisk contraction and urethra lumen closure when continence is challenged by sudden increases in intraabdominal pressure.

Innervation Important to Storage

When urine is being stored, the distention of the bladder wall stimulates low-level afferent vesical firing that, in turn, stimulates sympathetic outflow to the bladder base and urethra, and also pudendal outflow to the external urethra. This occurs by a spinal reflex pathway. The urogenital sphincter receives

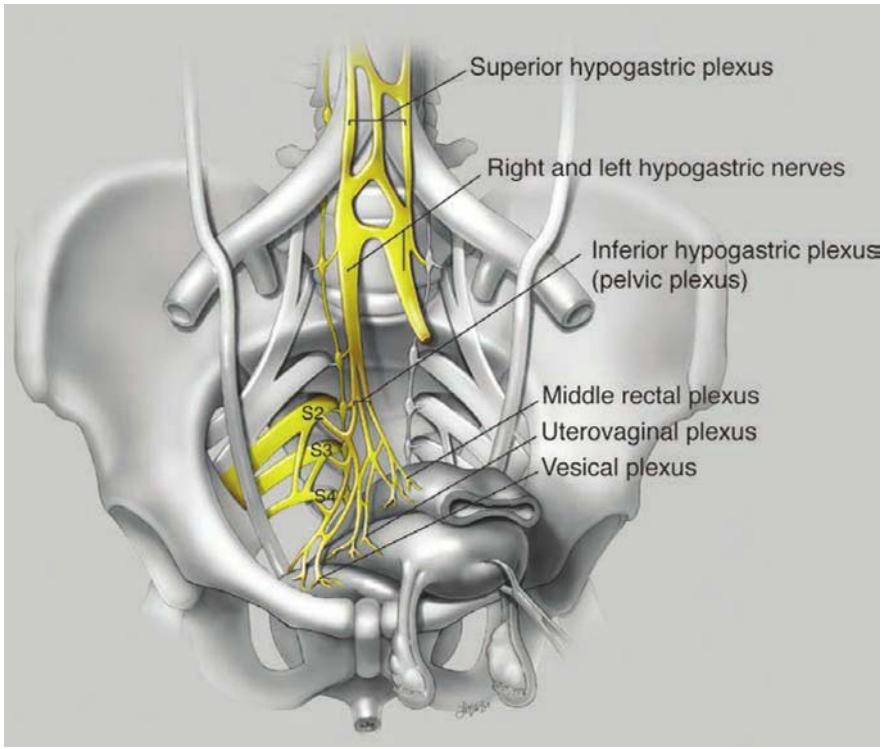

FIGURE 23-4 The inferior hypogastric plexus, also known as the pelvic plexus, is formed by visceral efferents from S2 to S4, which provide the parasympathetic component by way of the pelvic nerves. The superior hypogastric plexus primarily contains sympathetic fibers from the T10 to L2 cord segments and terminates by dividing into right and left hypogastric nerves. The hypogastric nerves and rami from the sacral portion of the sympathetic chain contribute the sympathetic component to the pelvic plexus. The pelvic plexus divides into three portions according to the course and distribution of its fibers: the middle rectal plexus, uterovaginal plexus, and vesical plexus. (Reproduced with permission from Lindsay Oksenberg.)

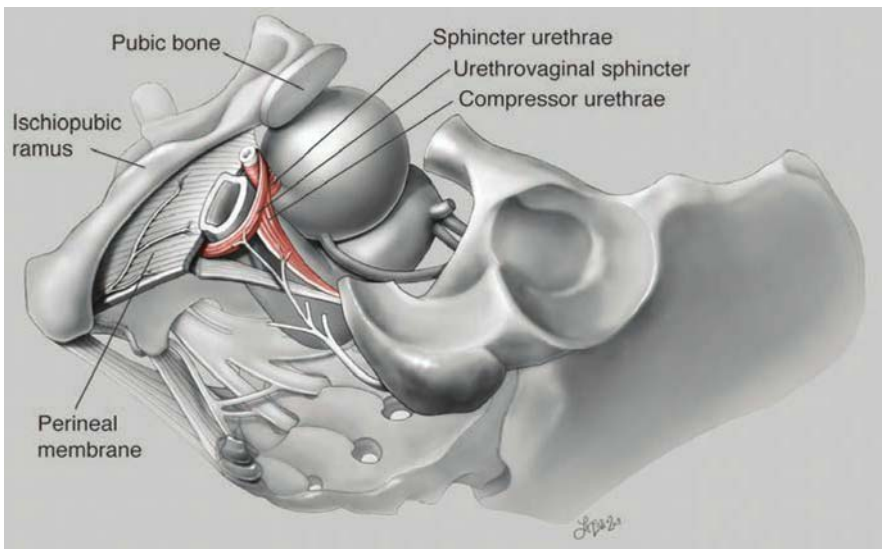

FIGURE 23-5 Striated urogenital sphincter anatomy. The perineal membrane is removed to show the three component muscles of the striated urogenital sphincter. This sphincter receives most of its somatic innervation through the pudendal nerve. (Reproduced with permission from Lindsay Oksenberg.)

somatic motor innervation through the pudendal and pelvic nerves (Fig. 23-6). Thus, pudendal neuropathy, which may follow obstetric injury, can affect normal sphincter functioning. Additionally, prior pelvic surgery or pelvic radiation therapy may damage nerves, vasculature, and soft tissue. Such injury can lead to ineffective urogenital sphincter action and contribute to incontinence. A region of the rostral pons known as the pontine storage center (or "L" region) also may increase activity of the external urethral sphincter.

Sympathetic fibers are carried through the superior hypogastric nerve plexus and communicate with α- and β-adrenergic receptors within the bladder and urethra. When norepinephrine binds to the β-adrenergic receptors in the bladder dome, it activates adenylate cyclase, which in turn raises levels of cyclic adenosine monophosphate and results in smooth-muscle relaxation and assists with urine storage (Fig. 23-7). β-Agonist medication may improve overactive

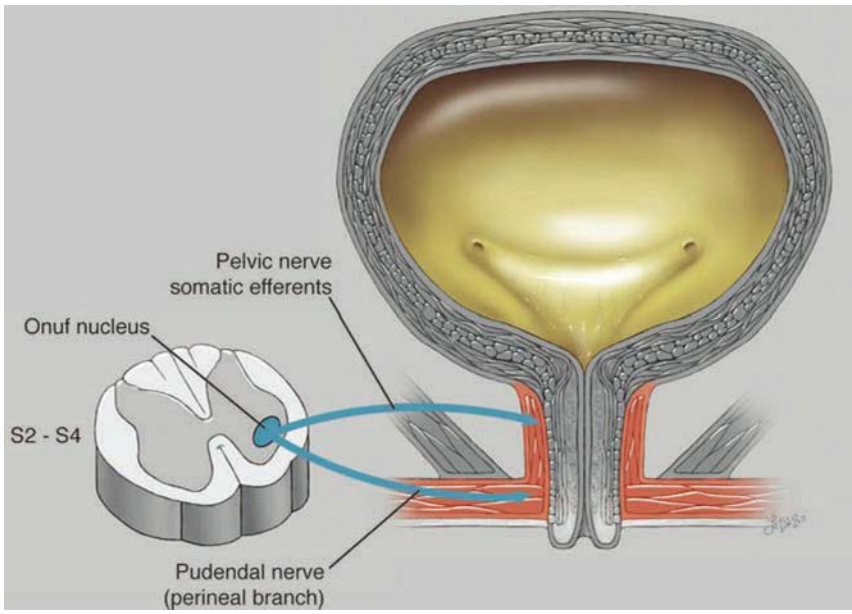

FIGURE 23-6 The Onuf nucleus is found in the ventral horn gray matter of S2 through S4. This nucleus contains the neurons whose fibers supply the striated urogenital sphincter. The urethrovaginal sphincter and compressor urethrae are innervated by the perineal branch of the pudendal nerve. The sphincter urethrae is variably innervated by somatic efferents that travel in the pelvic nerves. (Reproduced with permission from Lindsay Oksenberg.)

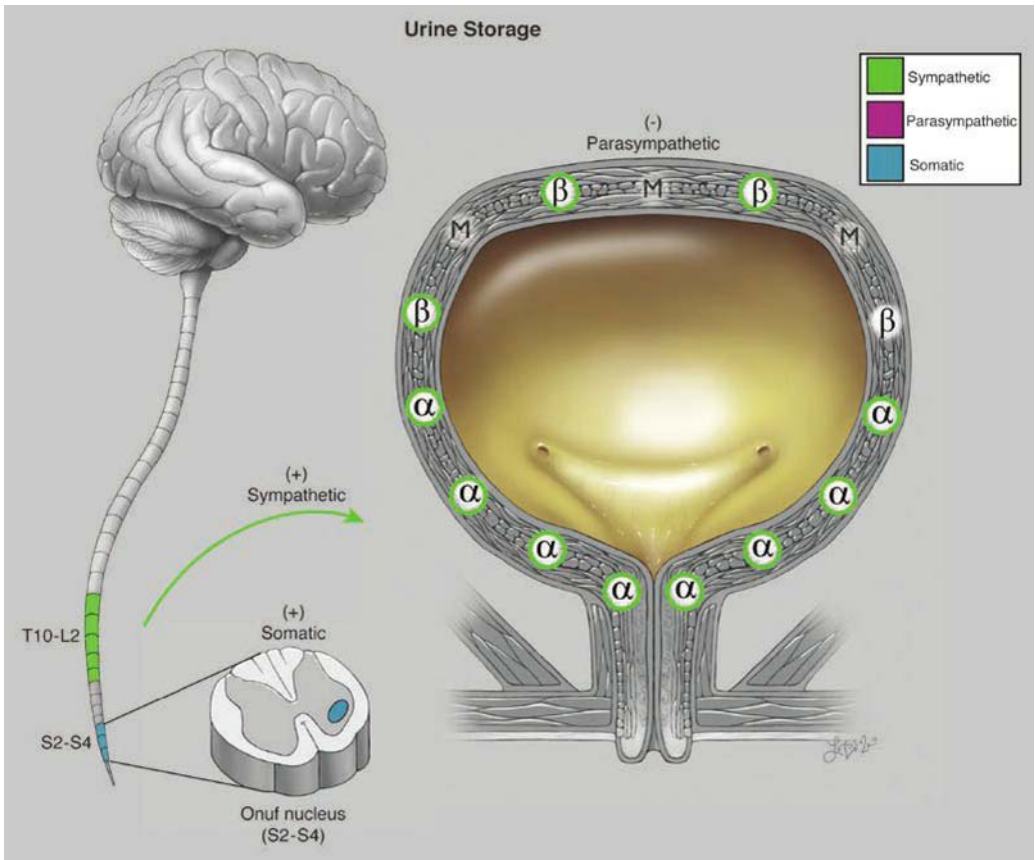

FIGURE 23-7 Physiology of urine storage. Bladder distention from filling leads to: (1) α-adrenergic contraction of the urethral smooth muscle and increased tone at the vesical neck (via the T11–L2 spinal sympathetic reflex); (2) activation of urethral motor neurons in the Onuf nucleus with contraction of striated urogenital sphincter muscles (via the pudendal nerve); and (3) inhibited parasympathetic transmission with decreased detrusor pressure. α = alpha adrenergic receptors; β = beta adrenergic; M = muscarinic (cholinergic). (Reproduced with permission from Lindsay Oksenberg.)

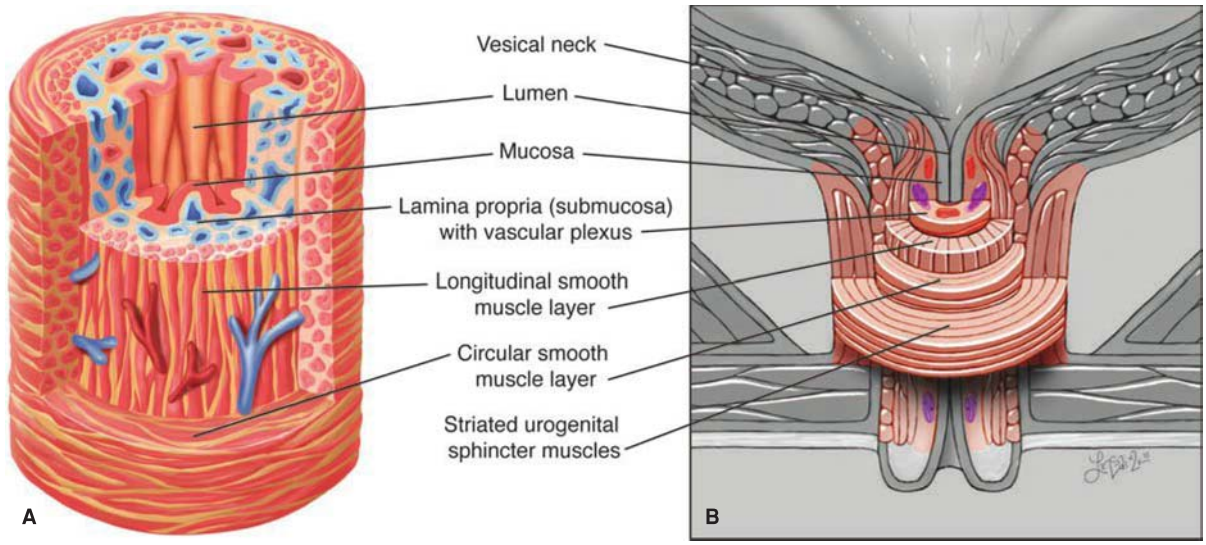

FIGURE 23-8 Drawing of urethral anatomy. **A.** Urethral anatomy in cross section. Urethral coaptation results in part from filling of the rich subepithelial vascular plexus. The urethra contains circular and longitudinal smooth muscle layers. **B.** Vesical neck and urethral anatomy. The striated urogenital sphincter lies external to the urethral smooth muscle layers. (Reproduced with permission from Lindsay Oksenberg.)

bladder symptoms through this mechanism of smooth-muscle relaxation. In contrast, α-adrenergic receptors predominate in the bladder base and urethra. These receptors are stimulated by norepinephrine, which initiates a cascade of events that preferentially leads to urethral contraction and aids urine storage and continence. These effects of α-stimulation underlie the treatment of SUI with imipramine, a tricyclic antidepressant with adrenergic agonist properties.

Urethral Coaptation

One key to continence is adequate urethral mucosal coaptation. The uroepithelium is supported by a connective tissue layer, which is thrown into deep folds, also known as *plications*. A rich capillary network runs within its subepithelial layer. This vascular network aids in urethral mucosal approximation, also termed *coaptation*, by acting like an "inflatable cushion" (Fig. 23-8). In women who are hypoestrogenic, this submucosal vasculature plexus is less prominent. In part, local hormone replacement targets this diminished vascularity and, in theory, enhances coaptation to improve continence.

Bladder Emptying

Innervation Related to Voiding

When an appropriate time for bladder emptying arises, sympathetic stimulation is reduced and parasympathetic stimulation is triggered via the pontine micturition center (or "M" region). Specifically, neural impulses carried in the pelvic nerves stimulate acetylcholine release and lead to detrusor muscle contraction (Fig. 23-9). Concurrent with detrusor stimulation, acetylcholine also stimulates muscarinic receptors in the urethra and leads to outlet relaxation for voiding while sympathetic outflow through the pudendal nerve to the urethral outlet is inhibited.

Within the parasympathetic division, acetylcholine receptors are broadly defined as muscarinic and nicotinic. The bladder is densely supplied with muscarinic receptors, which when stimulated lead to detrusor contraction. Of the muscarinic receptors, five glycoproteins designated M_1–M_5 have been identified. M_2 and M_3 receptor subtypes are predominantly responsible for detrusor smooth muscle contraction. Thus, treatment with muscarinic antagonist medication blunts detrusor contraction to improve continence. Specifically, continence drugs that target only the M_3 receptor maximize drug efficacy yet minimize activation of other muscarinic receptors and drug side effects.

Muscular Activity with Voiding

Smooth muscle cells within the detrusor fuse with one another so that a network of low-resistance electrical pathways extends from one muscle cell to the next. Thus, action potentials can spread quickly throughout the detrusor muscle to cause rapid contraction of the entire bladder. In addition, the plexiform arrangement of bladder detrusor fibers allows multidirectional contraction and is ideally suited for rapid concentric contraction during bladder emptying.

During voiding, all components of the striated urogenital sphincter relax. Importantly, bladder contraction and sphincter relaxation must be coordinated for effective voiding. Occasionally, the urethral sphincter fails to relax during contraction of the detrusor and urine retention ensues. Classically, this is a possible urinary complication of spinal cord injury termed *detrusor sphincter dyssynergia* and may lead to elevated bladder pressures and vesicoureteral reflux. Women with this condition are sometimes treated with α-blocking agents to help with sphincter relaxation and to lower bladder pressures during contraction, but these may aggravate hypotension. In women without known neurologic pathology but still with inappropriately contracted pelvic floor musculature, treatment with muscle relaxants may be appropriate. These drugs purportedly relax the urethral sphincter and levator ani muscles to improve coordinated voiding.

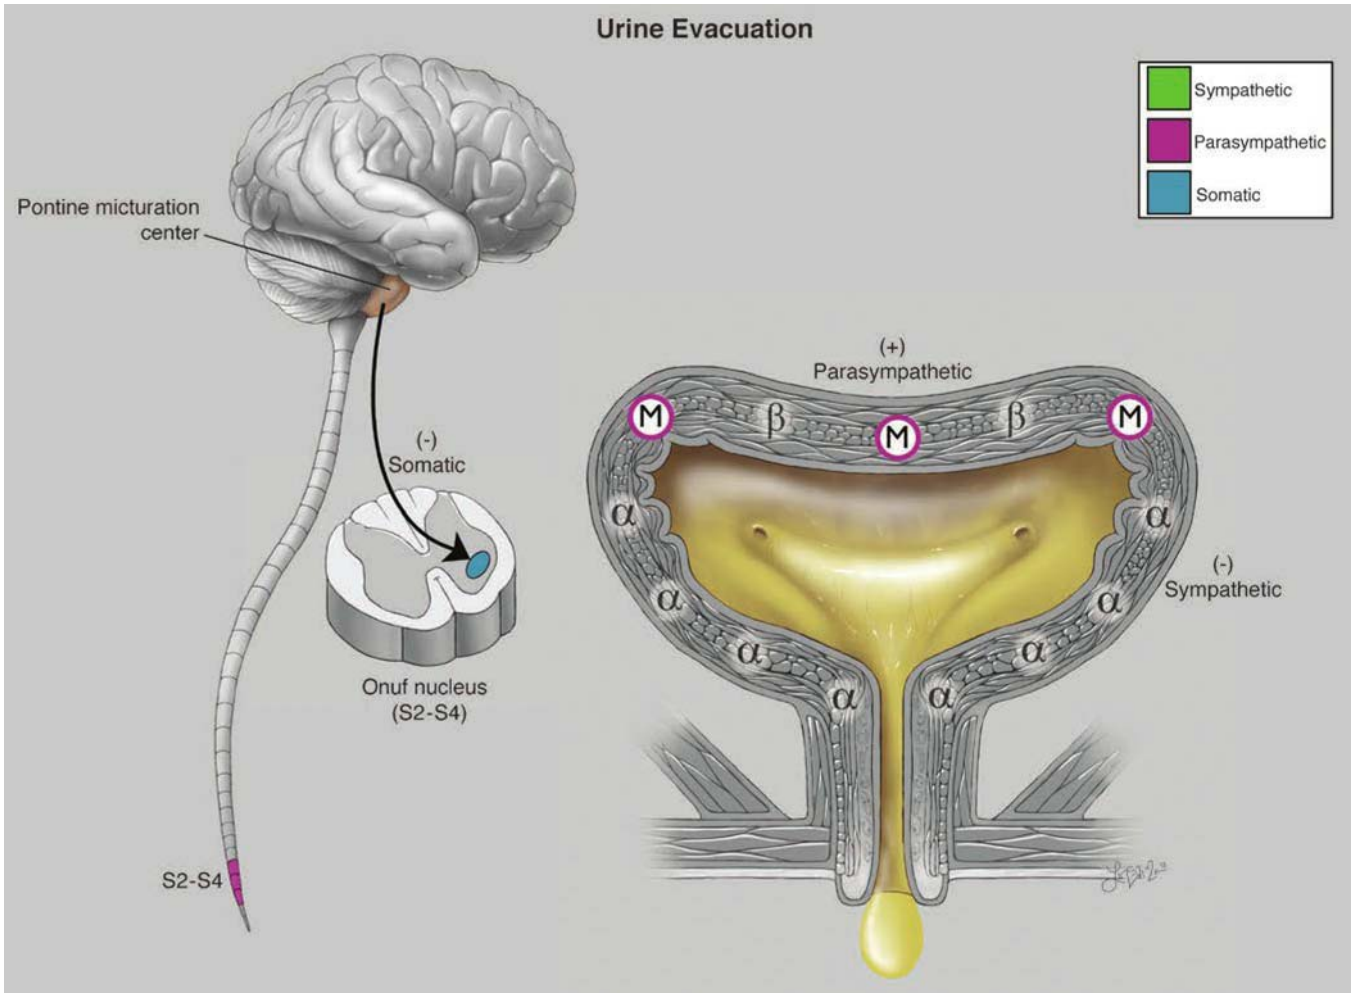

FIGURE 23-9 Physiology of urine evacuation. Efferent impulses from the pontine micturition center result in inhibition of somatic fibers in the Onuf nucleus and voluntary relaxation of the striated urogenital sphincter muscles. These efferent impulses also result in preganglionic sympathetic inhibition with opening of the vesical neck and parasympathetic stimulation, which results in detrusor muscarinic contraction. The net result is relaxation of the striated urogenital sphincter complex causing decreased urethral pressure, followed almost immediately by detrusor contraction and voiding. α = alpha adrenergic receptors; β = beta adrenergic; M = muscarinic (cholinergic). (Reproduced with permission from Lindsay Oksenberg.)

Incontinence Theories

Anatomic Stress Incontinence

Theories on incontinence vary in their supportive evidence but can simplistically be distilled into those that involve anatomic stress incontinence or those that describe diminished urethral integrity (sphincteric deficiency). These theories are not mutually exclusive, and both may be contributory in many women.

First, urethral and bladder neck support is integral to continence. This anatomic support derives from: (1) ligaments along the urethra's lateral aspects, termed the *pubourethral ligaments*; (2) the vagina and its lateral fascial condensation; (3) the arcus tendineus fascia pelvis; and (4) levator ani muscles. A full anatomic description of these ligaments and muscles is found in Chapter 38 (p. 808).

In an ideally supported urogenital tract, increases in intraabdominal pressure are equally transmitted to the bladder, bladder base, and urethra and are countered by supportive tissue tone provided by the levator ani muscles and vaginal connective tissue (Fig. 23-10). With loss of support, the ability of the urethra and bladder neck to close against a firm supportive "backboard" is diminished. This results in reduced urethral closing pressures, an inability to resist increases in bladder pressure, and, in turn, incontinence. This mechanistic theory is the basis for surgical reestablishment of this support. Traditional procedures such as Burch and Marshall-Marchetti-Kranz (MMK) colposuspensions attempt to return this anatomic support to the urethrovesical junction and proximal urethra.

Sphincteric Deficiency

Another way to conceptualize SUI is to consider the urethra as providing continence through the combination of: urethral mucosal coaptation, the underlying urethral vascular plexus, the combined viscous and elastic properties of the urethral epithelium, and contraction of appropriate surrounding musculature. Taken together, these components contribute to *urethral integrity*. Defects in any or a combination of these

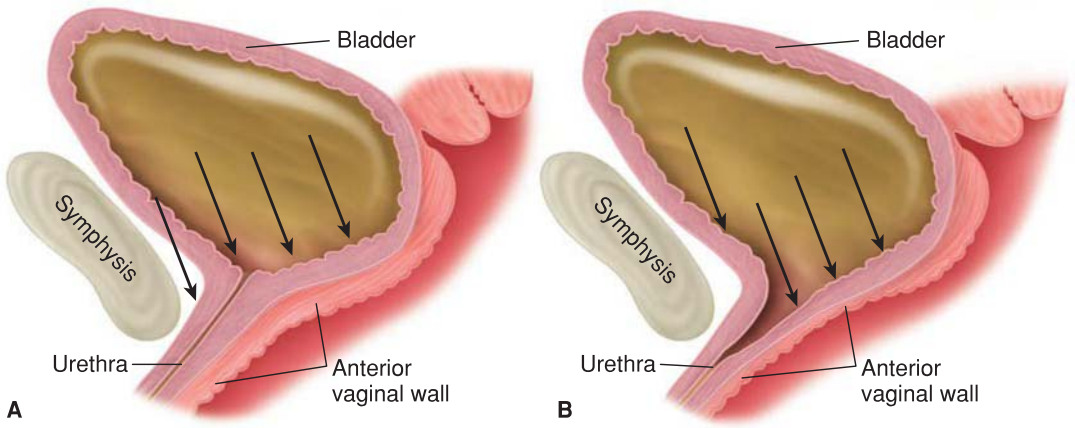

FIGURE 23-10 Drawing describes the "hammock hypothesis" theory of continence. **A.** Normal bladder neck support serves as a backboard for compression of the proximal urethra during increases in intraabdominal pressure. **B.** In those with poor urethral support, increases in intraabdominal pressure result in "funneling" of the urethra, and continence is lost.

components may lead to urine leakage and have traditionally been termed *intrinsic sphincteric deficiency (ISD)*. Prior surgery in the retropubic space may cause neuromuscular damage with denervation and scarring of the urethra and its supporting tissue. These effects subsequently prevent urethral closure and lead to incontinence. Specific causes are varied and include prior pelvic reconstructive surgeries, prior pelvic radiation therapy, diabetic neuropathy, neuronal degenerative diseases, and hypoestrogenism. With the last, women with atrophic lower genital tracts have vascular changes within the plexus surrounding the urethra that lead to poor coaptation and greater incontinence risks.

As noted earlier, nerve dysfunction following birth trauma may lead to defective urethral sphincter function (p. 513). In addition, childbirth also often injures urethral fascial support. This clinical example highlights the intimate relationship between urethral support and integrity.

Treatments to restore urethral integrity include transurethral injection of bulking agents, surgical sling procedures, and pelvic floor muscle strengthening, which are all described in later sections. In brief, bulking agents are placed at the urethrovesical junction to elevate the epithelium and promote coaptation. Sling procedures restore periurethral support anatomy or create partial urethral obstruction to enhance urethral integrity. Last, because the urethra exits through urogenital hiatus, levator ani muscle conditioning with Kegel exercises can bolster urethral integrity. These muscles can be contracted around the urethra when continence is challenged during sudden increases in intraabdominal pressures.

One concern with surgical management of patients with ISD, particularly those younger than 50 years, is that a retropubic colposuspension procedure merely elevates and stabilizes the urethra and does not promote coaptation. This may be less likely to achieve satisfactory continence than a procedure directed at both anatomic SUI and deficient urethral sphincter function and support (Sand, 1987). That said, a small trial randomizing incontinent women with ISD to Burch or sling procedures did not show differences in postoperative voiding function or in SUI cure rates (Culligan, 2003).

Detrusor Overactivity

Detrusor overactivity (DO) describes involuntary contractions of the bladder wall during filling cystometry (Abrams, 2009). The contractions may be spontaneous or provoked and may or may not be associated with a sense of urgency or urgency incontinence. Because it is a urodynamics study finding, DO cannot be used interchangeably with the *symptom* descriptions *overactive bladder* or *urgency urinary incontinence.* Nonetheless, DO is believed to underlie these last two. DO may be defined further by the qualifiers *neurogenic* (if a relevant neurologic condition is present) or *idiopathic*.

In neurogenic DO, neurologic lesions above the sacral level of the spinal cord block the sacral reflex arcs from the cerebral cortex and other higher centers that are important to bladder inhibition. This loss in inhibition permits involuntary detrusor muscle contractions yet appropriate relaxation of the urethral sphincter, which precipitates urgency urinary incontinence. This type of DO may occur with multiple sclerosis, cerebrovascular disorders, Parkinson disease, dementia, neoplasia, and spinal cord injury.

When no neurologic pathology is suspected—as is the more common scenario—this is described as idiopathic DO. Both neurogenic and myogenic hypotheses are proposed to explain idiopathic DO. The neurogenic explanation presumes generalized nerve-mediated excitation of the detrusor muscle. The myogenic explanation suggests a combination of heightened spontaneous excitation within the bladder smooth muscle and enhanced propagation and spread of contractile signals due to cell-to-cell coupling. Another interesting hypothesis possibly linked with idiopathic DO is the existence of bacterial DNA and live bacteria in the bladders of clinically uninfected patients. This constitutes the urinary microbiome. Cohorts with and without urgency urinary incontinence have qualitatively and quantitatively different urinary microbiomes. This suggests that either pathologic microbial species or the absence of protective ones could impact female urinary health (Pearce, 2014).

TABLE 23-2. The Three Incontinence Questions (3IQ)

1. During the last 3 months, have you leaked urine (even a small amount)?
   a. Yes (continue questions) b. No (questionnaire completed)
2. During the last 3 months, did you leak urine: (mark all that apply)
   a. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
   b. When you had the urge or feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
   c. Without physical activity and without a sense of urgency?
3. During the last 3 months, did you leak urine *most often*: (mark only one)
   a. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
   b. When you had the urge or feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
   c. Without physical activity and without a sense of urgency?
   d. About equally as often with physical activity as with a sense of urgency?

The response to question 3 with (a) or (b) indicates stress-predominant or urgency-predominant incontinence, respectively, whereas (d) indicates mixed and (c) suggests another cause of incontinence.

DIAGNOSIS

History

Symptom Clustering

Assessment of incontinence begins with a patient describing her urinary symptoms. These complaints may be collected through direct conversation but can be augmented with patient questionnaires. Two common forms are the Pelvic Floor Distress Inventory and the Pelvic Floor Impact Questionnaire. Both are available in long and short forms and evaluate urinary, bowel, and prolapse symptoms (Barber, 2001). Such lengthy research questionnaires may be impractical for general clinical practice. Instead, shorter validated questionnaires may easily be incorporated into the clinic setting. Shown in Table 23-2, the Three Incontinence Questions (3IQ) tool screens for incontinence and helps clarify incontinence type (Brown, 2006).

During inquiry, the number of voids and pads used per day, type of pad, frequency of pad changing, and the degree of pad saturation are important. Although these specifics alone may not establish the exact incontinence type, they do provide information regarding symptom severity and its effects on patient activities. If a woman's symptoms do not diminish her quality of life, simple observation is reasonable. Conversely, those with bothersome symptoms warrant further evaluation.

Specific to incontinence, information that describes the circumstances in which urine leaks and specific maneuvers that incite or provoke leakage are sought. With SUI, triggers may include increases in intraabdominal pressure such as coughing, sneezing, laughing, Valsalva maneuver, or deep penetration during intercourse. Alternatively, women with urgency urinary incontinence may describe urine loss after urge sensations that typically cannot be suppressed. *Overflow incontinence* was a term used in the past to refer to women who were unable to empty their bladder well but who also had involuntary, continuous urinary leakage or dribbling. Patients can sometimes have stress-like leakage when the bladder is very full or experience low-amplitude bladder contractions with symptoms more like urgency urinary incontinence. Currently, overflow incontinence is considered by many to reflect another presentation of urgency urinary incontinence. That said, it may still be a useful concept for understanding leakage as it is associated with either bladder outlet obstruction or detrusor *underactivity*. Of these, impaired bladder muscle contractility may be a consequence of aging, smooth muscle damage, fibrosis, hypoestrogenism, peripheral neuropathy (e.g., longstanding diabetes mellitus, vitamin B_{12} deficiency), or damage to spinal detrusor efferent nerves (e.g., multiple sclerosis or spinal stenosis) (Aldamanhori, 2017; Zimmern, 2014).

During questioning, symptoms typically cluster into those most frequently seen with SUI or with urgency urinary incontinence (see Table 23-2). Alternatively, a significant overlap of complaints may reflect mixed urinary incontinence. For these reasons, pattern identification is helpful as it may direct diagnostic testing and guide initial empiric therapy.

Voiding Diary

Typically, patients may not have an entirely accurate recollection of their own voiding habits. Accordingly, to obtain a thorough record, a woman ideally completes a urinary diary (Fig. 23-11). With this, the volumes and type of each oral fluid intake, volumes of urine with each void, episodes of urinary leakage, and triggers of incontinence episodes are recorded for 3 to 7 days. During each 24-hour period, women also record times of sleep and awakening to document voluntary nocturnal

Bladder Diary

Please record the time and amount of your oral intake, urine output, urine leakage, and pad changes FOR 3 DAYS

Time	Oral Intake	Voided Urine	Urine Leakage or Pad Change

FIGURE 23-11 Example of a urinary diary.

voiding patterns or enuresis. Three days usually suffice to determine the general trend of incontinence. Voiding frequency is normally less than eight times a day and once at night, and total volume voided in 24 hours is typically less than 1800 mL (Lukacz, 2009).

The information gained from a voiding/urinary diary is a valuable diagnostic and sometimes therapeutic tool. The first morning void is usually the largest of the day and is a good estimate of bladder capacity. Patients often can identify patterns in intake and voiding and modify behavior. For example, a patient may recognize increased urinary frequency or more urgency urinary incontinence episodes after caffeine intake. Moreover, this diary information can serve as a baseline against which treatment effectiveness can be assessed.

Urinary Symptoms

Of these, frequent voiding without increased oral fluid intake may indicate overactive bladder, UTI, calculi, or urethral pathology and often prompts additional evaluation. In addition, urinary frequency is commonly associated with interstitial cystitis/bladder pain syndrome (IC/BPS). With IC/BPS, the numbers of voids may commonly exceed 20 per day, and treatment is discussed in Chapter 12 (p. 268). Nocturia may be noted in women with urgency urinary incontinence or in those with systemic fluid management disorders such as congestive heart failure. In the latter case, treatment of the underlying condition often leads to symptom improvement or cure of nighttime frequency.

Urinary retention may provide clues. Often incomplete emptying can result in incontinence associated with either stress or urgency. Urethral obstruction, often manifested as an inability to void or an impeded urinary stream, is uncommon in women. Its description prompts careful evaluation for pelvic organ prolapse or pelvic mass. In addition, prior trauma or pelvic or vaginal surgery could scar or obstruct the urethra.

Of other urinary symptoms, the volume of urine lost with each episode may aid diagnosis. Large volumes are typically lost following a spontaneous detrusor contraction associated with urgency urinary incontinence and may often involve loss of the entire bladder volume. In contrast, women with SUI usually describe smaller volumes lost. Moreover, these women often are able to contract the levator ani muscles to temporarily stop their urine stream. Another symptom, postvoid dribbling, is classically associated with urethral diverticulum, which may often be mistaken for urinary incontinence (Chap. 26, p. 579). Hematuria, although a common sign of UTI, may also indicate underlying malignancy or stone and can cause irritative voiding symptoms.

Symptom onset also may prove informative. Problems beginning at menopause may suggest the hypoestrogenism that underlies genitourinary syndrome of menopause (GSM). Discussed in Chapter 22 (p. 495), patients may benefit from topical vaginal estrogen or the oral selective estrogen-receptor modulator (SERM) ospemifene (Osphena). In contrast, symptoms after hysterectomy or childbirth may reflect changes in tissue support or innervation.

Past Medical History

Obstetric trauma may be associated with damage to pelvic floor support, which may lead to SUI. Thus, a prolonged labor, operative vaginal delivery, macrosomia, or postpartum catheterization for urinary retention can be informative. As noted, urinary incontinence may be linked with several medical conditions or their treatments, which could be modified to improve incontinence. To help remember these potential contributors, a useful mnemonic is "DIAPPERS": dementia/delirium, infection, atrophic vaginitis, psychological, pharmacologic, endocrine, restricted mobility, and stool impaction (Swift, 2008).

First, continence requires the cognitive ability to recognize and react appropriately to the sensation of a full bladder, motivation to maintain dryness, sufficient mobility and manual dexterity, and ready access to a toilet. Patients with dementia or significant psychological impairments often do not have the necessary cognitive ability for continence. Women with severe physical handicaps or restricted mobility may simply not have time to reach the toilet. For this so-called *functional incontinence*, simple interventions such as a bedside commode may be helpful.

UTIs cause bladder mucosal inflammation. This inflammation is thought to enhance sensory afferent activity, which contributes to an overactive bladder. Women prone to UTIs commonly experience urinary incontinence, both between UTI episodes and especially worse in the midst of an acute infection (Moore, 2008). Similarly, hypoestrogenism can lead to atrophic vaginal and urethral epithelia and may be associated with increased irritation and greater risks of UTI and overactive bladder.

A detailed medication inventory is collected. Pertinent drugs include estrogen, α-adrenergic agonists, caffeine, alcohol, and diuretics, to name a few (Table 23-3).

Of endocrinopathies, diabetes mellitus can promote osmotic diuresis and polyuria if glucose control is poor. Excessive caffeine or alcohol intake or polydipsia from diabetes insipidus can also lead to polyuria or urinary frequency. Similarly, other disorders of impaired arginine vasopressin secretion or action may cause polyuria and nocturia (Ouslander, 2004). Conditions such as congestive heart failure, hypothyroidism, venous insufficiency, and the effects of certain medications all contribute to peripheral edema, leading to urinary frequency and nocturia once a patient is supine.

Last, stool impaction resulting from poor bowel habits and constipation can contribute to overactive bladder symptoms. This is perhaps from local irritation or direct compression against the bladder wall.

Physical Examination

General Inspection and Neurologic Evaluation

Initially, the perineum is inspected for evidence of atrophy, which may be noted throughout the lower genital tract. In addition, a suburethral cystic mass or dilation with transurethral expression of fluid during compression suggests a urethral diverticulum (Fig. 26-7, p. 582).

Examination of an incontinent woman also includes a detailed neurologic evaluation of the perineum. Because

TABLE 23-3. Medications That May Contribute to Incontinence

Medication	Examples	Mechanism	Effect
Alcohol	Beer, wine, liquor	Decreased bladder contractility, diuretic effect, sedation, immobility	Polyuria, frequency
α-Adrenergic agonists	Midodrine, phenylephrine, various vasopressors, decongestants, diet pills	IUS contraction	Urinary retention
α-Adrenergic blockers	Prazosin, terazosin, doxazosin, alfuzosin, silodosin	IUS relaxation	Urinary leakage
Anticholinergic agents		Inhibit bladder contraction, sedation, fecal impaction	Urinary retention and/or functional incontinence
Antihistamines	Diphenhydramine, hydroxyzine, scopolamine, dimenhydrinate		
Antipsychotics	Thioridazine, chlorpromazine, haloperidol		
Antiparkinsonians	Trihexyphenidyl, benztropine mesylate		
Miscellaneous	Dicyclomine, disopyramide		
Skeletal muscle relaxants	Orphenadrine, cyclobenzaprine		
Tricyclic antidepressants	Amitriptyline, imipramine, nortriptyline, doxepin		
ACE inhibitors	Enalapril, captopril, lisinopril, losartan	Chronic cough, decreased bladder contractility	Urinary leakage
Calcium-channel blockers	Nifedipine, nicardipine, isradipine, felodipine	Relaxes bladder, fluid retention	Urinary retention, nocturnal diuresis
COX-2 inhibitors	Celecoxib	Fluid retention	Nocturnal diuresis
Diuretics	Caffeine, HCTZ, furosemide, bumetanide, acetazolamide, spironolactone	Increases urinary frequency, urgency	Polyuria
Narcotic analgesics	Opiates	Relaxes bladder, fecal impaction, sedation	Urinary retention, and/or functional incontinence
Thiazolidinediones	Rosiglitazone, pioglitazone, troglitazone	Fluid retention	Nocturnal diuresis

ACE = angiotensin-converting enzyme; COX-2 = cyclooxygenase-2; HCTZ = hydrochlorothiazide; IUS = internal urethral sphincter; NSAID = nonsteroidal antiinflammatory drug.

neurologic responses may be altered in an anxious patient who is in a vulnerable examination setting, signs elicited during evaluation may not signify true pathology and are interpreted in context and with caution. We usually begin neurologic evaluation with an attempt to elicit a *bulbospongiosus reflex*, by stroking one labium majus with a cotton swab. Generally, both labia contract at the same time. The afferent limb of this reflex is the clitoral branch of the pudendal nerve, whereas its efferent limb is conducted through the inferior hemorrhoidal branch of the pudendal nerve. This reflex is integrated at the S2–S4 spinal cord level (Wester, 2003). Thus, reflex absence may suggest central or peripheral neurologic deficits. Second, a normal circumferential anal sphincter contraction, colloquially called an *anal wink*, should follow cotton swab brushing of the perianal skin. External urethral sphincter activity requires at least some degree of intact S2–S4 innervation, and this *anocutaneous reflex* is mediated by the same spinal neurologic level. Thus, an absent wink may indicate deficits in this neurologic distribution.

Pelvic Support Assessment

Poor urethral support commonly accompanies pelvic organ prolapse (POP). Women with significant POP are often unable to completely empty their bladder due to urethral kinking and obstruction. These women frequently must digitally elevate or reduce their prolapse to allow emptying. Thus, an external evaluation for POP, described in Chapter 24 (p. 544), is indicated for all women with urinary incontinence. Following

this evaluation for vaginal compartment defects, pelvic muscle strength also is assessed. Women with mild to moderate urinary incontinence often respond well to pelvic floor therapy, and under these circumstances, a trial of this therapy is warranted and often curative (p. 527).

Lack of distal anterior vaginal wall support can lead to urethral hypermobility during increased intraabdominal pressure. In patients with descent to the level of the hymen or beyond with Valsalva, urethral hypermobility is universal (Noblett, 2005). In those with SUI and lesser anterior vaginal wall prolapse, a *Q-tip test* may provide a more objective assessment of urethral hypermobility. However, the test is now a less-essential part of pelvic floor assessment due to associated urethral pain and its poor predictive value for antiincontinence surgery success.

If performed, the soft end of a cotton swab is placed into the urethra to the urethrovesical junction. Failure to insert the swab to this depth can lead to assessment errors. An application of intraurethral analgesia may prove helpful, and 1-percent lidocaine jelly is placed on the cotton swab prior to insertion. Following placement, a Valsalva maneuver is prompted, and the swab-excursion angle at rest and with Valsalva maneuver is measured. An angle change or a resting angle >30 degrees above the horizon suggests urethral hypermobility.

Bimanual and Rectovaginal Examination

In general, these portions of the pelvic examination provide fewer diagnostic clues to underlying incontinence causes. However, bimanual examination may reveal a pelvic mass or a uterus enlarged by leiomyomas or adenomyosis. These can create incontinence through increased external pressure transmitted to the bladder. In addition, stool impaction is easily identified with rectal examination.

Diagnostic Testing

Urinalysis and Culture

In all women with urinary incontinence, infection or urinary tract pathology must be excluded. Urinalysis and urine culture are sent at an initial visit, and infection is treated as described in Table 3-14 (p. 77). Persistent irritative voiding symptoms, despite appropriate antibiotic treatment, warrant additional evaluation for other conditions such as IC/BPS.

Postvoid Residual Volume

This volume is routinely measured during incontinence evaluation. After a woman voids, the postvoid residual (PVR) volume may be measured by transurethral catheterization or with a handheld sonographic bladder scanner. The latter is a portable 3-dimensional ultrasound device that scans the bladder and provides numeric results (Fig. 23-12). In general, they are quick, easy to use, and more comfortable for the patient. However, if using a handheld scanner, care must be taken in women with a leiomyomatous uterus or other pelvic mass, as these may yield a falsely large PVR reading. In these instances, or if a scanner is not available, transurethral catheterization may be used to obtain the residual bladder volume.

FIGURE 23-12 Handheld bladder scanner aids estimation of bladder volume.

A large PVR volume may reflect recurrent infection, urethral obstruction from a pelvic mass, or neurologic deficits. In contrast, a normal, small PVR volume is often found in those with SUI. After continence surgery, PVR measurement is a helpful indicator of a patient's ability to completely empty her bladder. Postoperative PVR volume determination and voiding trials are described in Chapter 42 (p. 919).

Urodynamic Studies

Surgical correction of incontinence is invasive and not without risk. However, the "bladder is an unreliable witness," and historical information may not always accurately indicate the true underlying type of incontinence (Blaivas, 1996). Thus, if initial conservative management is unsuccessful or surgical treatment is anticipated, objective assessment is pursued. In addition, if symptoms and physical findings are incongruous, then objective *urodynamic studies (UDS)*, using simple or multichannel cystometrics, also may be indicated. For example, in a woman with mixed urinary incontinence, who has symptoms of both stress and urgency urinary incontinence, UDS may reveal that only the urgency component is responsible for her incontinence. These cases are treated with behavioral, physical, and/or pharmacologic therapy initially. Thus, if identified by UDS, these individuals can avoid unnecessary surgery. Additionally, surgical therapy may be modified if UDS reveals parameters consistent with ISD.

Despite these indications, UDS remains controversial. Leakage noted during testing is not always clinically relevant. In addition, testing may be uninformative if the original offending maneuver or situation that led to incontinence cannot be reproduced during testing. Moreover, objective confirmation of the diagnosis is not always necessary, since empiric nonsurgical therapy in women with urgency-predominant symptoms is reasonable. Also, for women with stress-predominant

urinary incontinence undergoing surgical treatment, outcomes were no different 1 year later in those screened by UDS compared with those evaluated by a simple office evaluation. Office testing included demonstrable leakage during examination, urine analysis without infection, and PVR volume <150 mL (Nager, 2012).

Simple Cystometrics. Objective measurement of bladder function, that is, UDS, combines a battery of tests termed *cystometrics*, which may be *simple* or *multichannel*. Simple cystometrics allows determination of SUI and detrusor overactivity and measurement of first sensation, desire to void, and bladder capacity. This procedure is easily performed with room-temperature sterile normal saline, 60-mL catheter-tipped syringe, and urinary catheter, either Foley or Rob-Nel. The urethra is sterilely prepared, the catheter is inserted, and the bladder is drained. A 60-mL syringe with its plunger removed is attached to the catheter and is filled upright with sterile water. Water is added in increments until a woman feels a sensation of bladder filling, urge to void, and bladder maximum capacity. A normal bladder capacity for most women ranges from 300 to 700 mL. Changes in the fluid meniscus within the syringe are monitored. In the absence of a cough or Valsalva maneuver that would raise intraabdominal pressure, an abrupt meniscus elevation indicates bladder contraction and suggests detrusor overactivity. Once bladder capacity is reached, the catheter is removed, and the woman is asked to perform a Valsalva maneuver or cough while standing. Leakage directly linked to these increases in intraabdominal pressure indicates SUI.

Simple cystometrics require inexpensive equipment and can typically be completed by most gynecologists. One limitation, however, is its inability to assess for ISD, which may preclude certain surgical options. Multichannel cystometrics can evaluate for ISD and thus may offer advantages. An interesting potential application of simple cystometrics is in the evaluation of the *continent* patient planning surgery for POP. With 300 mL of saline instilled in the bladder and vaginal prolapse reduced with large cotton swabs, some patients will demonstrate leakage with cough or Valsalva—perhaps when standing if not seen supine. In these women with "potential" or "occult" SUI, some may consider a prophylactic continence procedure. Available decision-aid tools attempt to quantify the risk of this unmasked incontinence to help patients balance concomitant continence surgery benefits and risks (Jelovsek, 2014; Wei, 2012).

Multichannel Cystometrics. This UDS type provides more information on other physiologic bladder parameters than simple cystometrics. Multichannel cystometrics more commonly is performed by urogynecologists or urologists due to the expense and limited availability of needed equipment. Testing can be performed with a woman standing or seated upright in a specialized testing chair. During evaluation, two catheters are used. One is placed into the bladder and the other into either the vagina or rectum. The vagina is preferred unless advanced POP is evident, as stool in the rectal vault may obstruct catheter sensors and lead to inaccurate readings. Additionally, vaginal placement for most women is more comfortable. From each of these two catheters, distinct pressure readings are obtained or calculated. These include: (1) intraabdominal pressure, (2) vesicular pressure, (3) calculated detrusor pressure, (4) bladder volume, and (5) saline-infusion flow rate. Shown in Figures 23-13 and 23-14, the various incontinence forms can be differentiated.

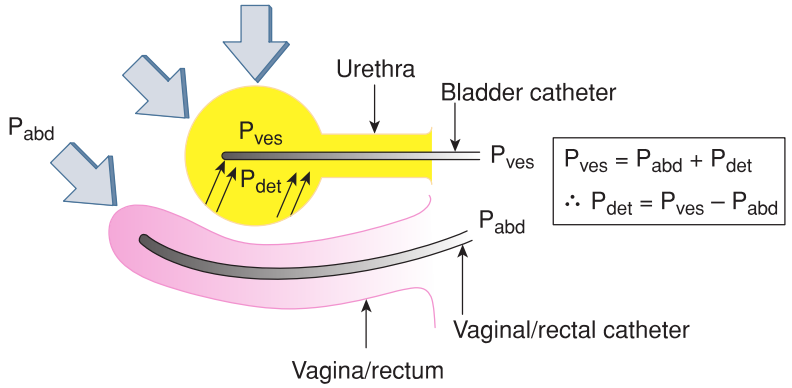
Uroflowmetry. Initially, a woman is asked to empty her bladder into a commode connected to a flowmeter (uroflowmetry). After a maximal flow rate is recorded, the patient is catheterized to measure PVR volume and to ensure an empty bladder prior to further testing. This test provides information on a woman's ability to empty her bladder and can identify women with urinary retention and other types of voiding dysfunction. Presuming that a patient begins with a comfortably full bladder of 200 mL or greater, most patients can empty their bladder over 15 to 20 seconds with flow rates >20 mL/s. Maximum flow rates <15 mL/s, with a voided volume >200 mL, are generally considered abnormally slow. In this setting—especially if accompanied by urinary retention—voiding dysfunction is identified. This may signal obstruction from a kinked urethra, which can result from anterior vaginal wall prolapse or from postoperative antiincontinence support that is too tight. As another example, voiding dysfunction may reflect neurologic dysfunction and poor detrusor contractility, as in those with longstanding poorly controlled diabetes.

Cystometrography. Following uroflowmetry, cystometrography is performed to determine whether a woman has urodynamic stress incontinence (USI) or detrusor overactivity (DO). Additionally, this test provides information on bladder threshold volumes at which a woman senses bladder capacity. Delayed sensation or sensation of bladder fullness only with large capacities may indicate neuropathy. Conversely, extreme bladder sensitivity may suggest sensory disorders such as IC/BPS.

For the cystometrogram, a small (approximately 7F) catheter with a pressure transducer at its tip is inserted transurethrally into the bladder and a second similar catheter is inserted into the vagina or rectum (see Fig. 23-14). While the patient is seated, the bladder is filled with room-temperature sterile normal saline, and the patient is asked to cough at regular intervals. Additionally, during filling, the volumes at which a first desire to void and maximal bladder capacity is reached are noted. From pressure readings, DO and/or USI may be identified.

After cystometrography, once approximately 200 mL of saline has been instilled, an abdominal *leak point pressure* is measured. The patient is asked to perform a Valsalva maneuver, and the pressure generated by the effort is measured and evidence of urine leakage is sought. If leakage is seen when a pressure of <60 cmH_2O is generated, criteria have been met for a diagnosis of ISD. At our institution, abdominal leak point pressures are measured at a bladder volume of 200 mL, using the true zero of intravesical pressure as the baseline. However, the volume at which this test is performed varies among institutions, with some choosing to use bladder capacity and others choosing to use 150 mL as the testing volume.

Pressure Flowmetry. This evaluation usually follows cystometrography and is similar to the uroflowmetry conducted



Clinical scenario	I a.	I b.	II a.	II b.
P_{abd} (abdominal pressure) [vaginal/rectal catheter]	∩	∩	—	∩
P_{ves} (bladder pressure) [bladder catheter]	∩	∩	∩	∧
P_{det} (true detrusor pressure) [subtracted/calculated]	—	—	∩	∩
Leakage	⊕	⊖	⊕ or ⊖	⊕ or ⊖
Diagnosis	USI	No USI	DO	DO

FIGURE 23-13 Interpretation of multichannel urodynamic evaluation: cystometrogram. A catheter is placed in the bladder to determine the pressure generated within it (P_{ves}). The pressure in the bladder is produced from a combination of the pressure from the abdominal cavity and the pressure generated by the detrusor muscle of the bladder. Bladder pressure (P_{ves}) = Pressure in abdominal cavity (P_{abd}) + Detrusor pressure (P_{det}). A second catheter is placed in the vagina (or rectum if advanced-stage prolapse is present) to determine the pressure in the abdominal cavity (P_{abd}). As room temperature water is instilled into the bladder, the patient is asked to cough every 50 mL and the external urethral meatus is observed for leakage of urine around the catheter. The volume at first desire to void and the bladder capacity is recorded. Additionally, the detrusor pressure (P_{det}) channel is observed for positive deflections to determine if there is detrusor activity during testing. The detrusor pressure (P_{det}) cannot be measured directly by any of the catheters. However, from the first equation, we can calculate the detrusor pressure (P_{det}) by subtracting the abdominal pressure (P_{abd}) from the bladder pressure (P_{ves}):

Detrusor pressure (P_{det}) = Bladder pressure (P_{ves}) − Pressure in abdominal cavity (P_{abd})

I. Urodynamic Stress Incontinence (USI)

Urodynamic stress incontinence is diagnosed when urethral leakage is seen with increased abdominal pressure, in the *absence* of detrusor pressure.

a. +USI (Column 1): Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure (P_{ves}) is noted. The calculated detrusor pressure is zero. Leakage is observed and diagnosis of USI is assigned.

b. No USI (Column 2): Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure (P_{ves}) is noted. The calculated detrusor pressure is zero. Leakage is *not* observed. The patient is *not* diagnosed as having USI.

II. Detrusor Overactivity (DO)

Detrusor overactivity is diagnosed when the patient has involuntary detrusor contractions during testing with or without leakage.

a. +DO (Column 3): Although no abdominal pressure is observed, a vesicular pressure is noted. A calculated detrusor pressure is recorded and noted to be present. A diagnosis of DO is made regardless of whether leakage is seen or not.

b. +DO (Column 4): In this example, an abdominal pressure as well as a vesicular pressure is observed. Using only the P_{abd} and the P_{ves} channels, it is difficult to tell whether the detrusor muscle contributed to the pressure generated in the bladder. On subtraction, a calculated detrusor pressure is recorded. Thus, a diagnosis of DO is made, again regardless of whether leakage is seen.

In addition to these channels, occasionally a channel to detect electromyographic activity is used.

Flow rate = rate of fluid infusion (usually 100 mL/min); P_{abd} = pressure in abdominal cavity; P_{det} = detrusor pressure (calculated); P_{ves} = bladder pressure; Vol = volume of fluid instilled in the bladder.

at the beginning of urodynamic testing. A woman is asked to void into a large beaker that rests on a calibrated weighted sensor. Maximum flow rate and postvoid residual volume are once again recorded. Similar to uroflowmetry, the output from the urodynamics instrumentation provides a graphical representation of the void. However, during voiding, a woman now has a microtip transducer catheter in her bladder, which provides an additional display of detrusor pressure during the void, including pressures at the point of maximum flow rate. This is particularly useful in women who may have incomplete bladder emptying. In this instance, pressure flowmetry may suggest either an obstructive scenario (elevated maximal detrusor

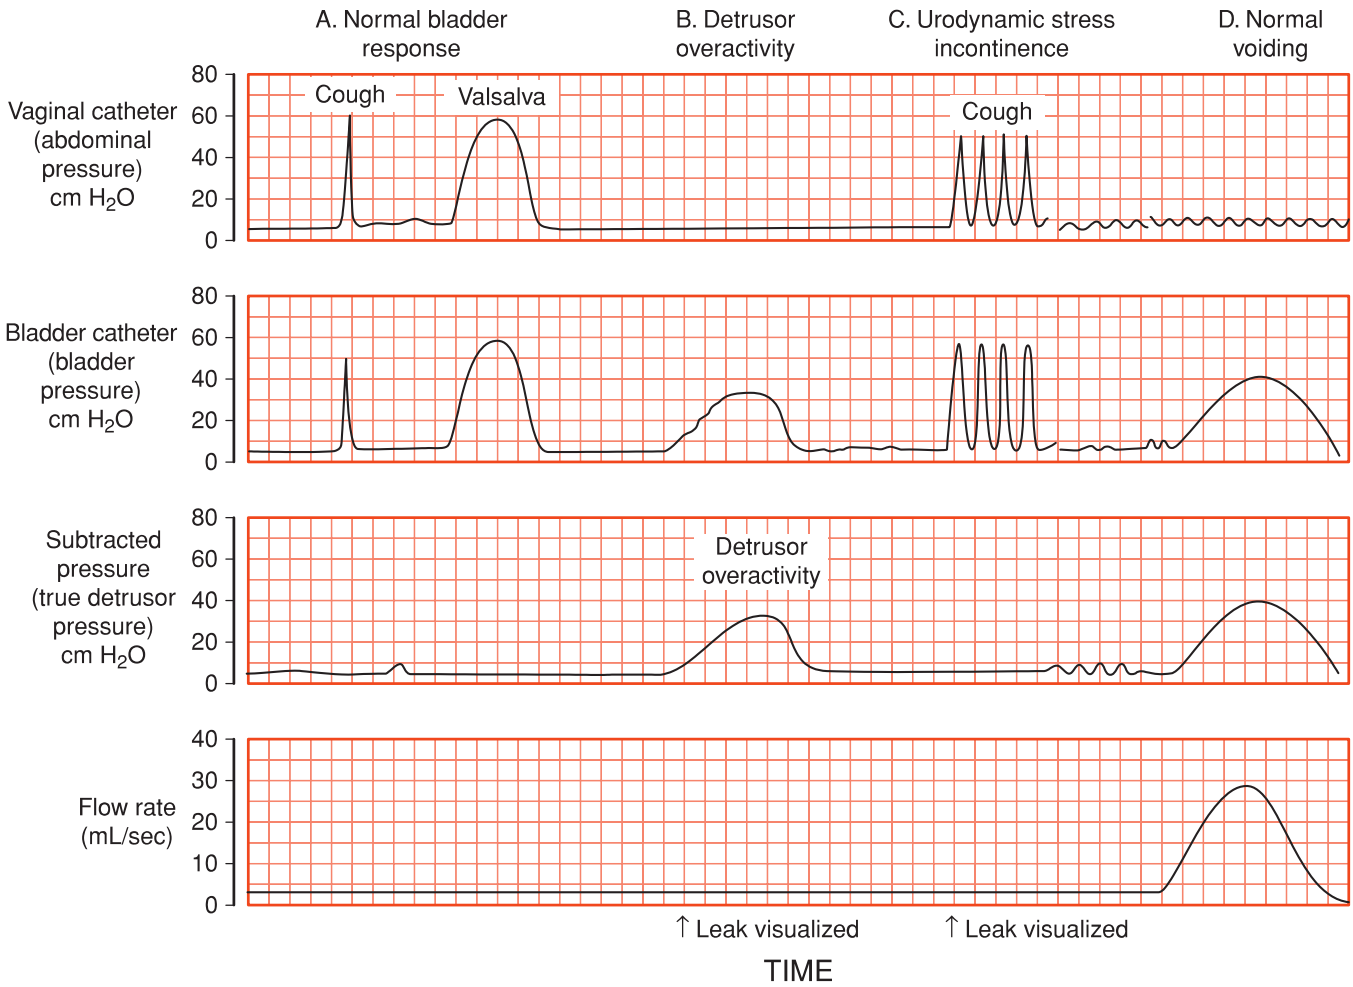


FIGURE 23-14 Multichannel cystometrics. **A.** A patient with normal function. Note that provocation by coughing or Valsalva maneuver does not provoke an abnormal rise in detrusor pressure. **B.** A patient with combined detrusor overactivity and urodynamic stress incontinence. First, spontaneous detrusor activity leads to increased bladder pressure reading in the absence of cough or Valsalva maneuver. **C.** Second, a cough alone leads to urine leakage, independent of detrusor muscle activity. **D.** At maximum capacity and on command, a detrusor contraction is generated and voiding is initiated.

pressure with slow flow rate) or poor detrusor contractility (low detrusor pressure and slow flow rate).

Urethral Pressure Profile. The final part of cystometric testing is the urethral pressure profile. At our institution, we usually perform this test in the seated patient with a volume of 200 mL instilled in the bladder. However, again, this volume is often institution dependent. A catheter transducer is positioned within the bladder, and the microtip dual-sensor catheter is pulled through the urethra with the aid of an automated puller arm at a speed of 1 mm/sec. Maximum urethral closure pressure (MUCP) is determined by averaging the pressure from three pull-throughs of the thin 7F catheter. As such, the MUCP values provide important information on the intrinsic properties of the urethra and aid in diagnosis of ISD. A diagnosis of ISD is made if the MUCP is <20 cmH_2O or, as described in the last section, if the leak point pressure is <60 cmH_2O (McGuire, 1981). These terms and concepts provide the rationale for procedures aimed at correcting stress incontinence. Importantly, the values used to define ISD are not well standardized and inconsistently predict surgical outcome (Monga, 1997; Weber, 2001).

TREATMENT

Conservative/Nonsurgical

Pelvic Floor Strengthening

Conservative management is a reasonable initial and generally recommended approach to most patients with urinary incontinence. The rationale behind conservative management is to strengthen the pelvic floor and provide a supportive "backboard" against which the urethra may close. For both SUI and urgency urinary incontinence, these fundamentals prove valuable. With SUI, pelvic floor strengthening attempts to compensate for anatomic support defects. For urgency urinary incontinence, it intensifies pelvic floor muscle contractions to provide temporary continence during waves of involuntary bladder detrusor contraction. For strengthening, options include active pelvic floor exercises and occasionally passive electrical pelvic floor muscle stimulation.

Active pelvic floor muscle training (PFMT) may lessen, if not cure, urinary incontinence in women who have mild to moderate symptoms. Also known as *Kegel (pronounced "Kay-gull") exercises*, PFMT entails voluntary contraction of the levator ani muscles.

Exercise sets are performed a number of times during the day, with some reporting up to 50 or 60 times each day. However, specific details of these exercise regimens vary according to provider preference and may be individualized according to the clinical presentation and muscle recruitment abilities of the patient.

In other PFMT protocols, a woman is asked to squeeze and hold contracted levator ani muscles. Women, however, often have difficulty isolating these muscles. Frequently, patients will erroneously contract their abdominal wall muscles. To help localize the correct muscle group, in an office setting, contraction of the levator ani muscle complex can be palpated through the vagina by the practitioner to provide direct and immediate feedback to the patient (Fig. 12-4, p. 260). Instructing the patient to identify the muscles that are tightened when snug pants are pulled up and over her hips is another suggestion that may help patients with correct muscle isolation.

At our institution, we aim to help patients achieve a sustained pelvic floor contraction of 10 seconds. A typical PFMT regimen begins with the contraction duration a patient can sustain (e.g., 3 seconds) and ask them to hold for this long and then relax for one to two times this duration (e.g., 6 seconds). This squeeze and release is repeated 10 to 15 times. Three sets are performed throughout the day for a total of approximately 45 contractions. Within weeks and with frequent follow-up visits, the contraction duration and pelvic floor muscle tone steadily increase. As a result, patients with SUI are usually able to more forcefully squeeze their muscles in anticipation of sudden increases in intraabdominal pressure.

Alternatively, a woman may be asked to rapidly contract and relax the levator ani muscles. These "quick flicks" may prove advantageous if waves of urinary urgency strike. Of note, no advantage is gained by stopping actual midstream urination, and women are counseled that this practice may worsen voiding dysfunction.

To augment exercise efficacy, weighted vaginal cones or obturators may be placed into the vagina during Kegel exercises. These provide resistance against which pelvic floor muscles can work.

PFMT for women with urinary incontinence compared with no treatment, placebo or sham treatment, or other inactive control treatment has been reviewed (Dumoulin, 2018). Although interventions vary considerably, women who performed PFMT are more likely to report cure or improved incontinence and enhanced continence-specific quality of life than women who did not use PFMT. The exercising women also objectively demonstrated less leakage during office-based pad testing. Prognostic indicators that may predict a poor response to PFMT for SUI treatment include severe baseline incontinence, prolapse beyond the hymenal ring, prior failed physiotherapy, history of prolonged second-stage labor, BMI >30 kg/m^2, high psychological distress, and poor overall physical health (Hendriks, 2010).

As an alternative to active pelvic floor contraction, a vaginal probe can deliver low-frequency electrical stimulation to the levator ani muscles. Although the mechanism is unclear, this passive electrical stimulation may improve either SUI or urgency urinary incontinence (Indrekvam, 2001; Wang, 2004). With urgency urinary incontinence, a low frequency is traditionally applied, whereas for SUI, higher frequencies are used. Electrical stimulation may be implemented alone or more commonly in combination with active PFMT.

Many behavioral techniques, often considered together as *biofeedback therapy*, measure physiologic signals such as muscle tension and then display them to a patient in real time. In general, visual, auditory, and/or verbal feedback cues are directed to the patient during these therapy sessions. Specifically, during biofeedback for active PFMT, a sterile vaginal probe that measures pressure changes within the vagina during levator ani muscle contraction is commonly used. Visual readings reflect an estimate of muscle contraction strength. Treatment sessions are individualized, dictated by the underlying dysfunction, and modified based on response to therapy. In many cases, reinforcing sessions at various subsequent intervals may also prove advantageous.

Dietary

Various food groups that may have high acidity or caffeine content can lead to greater urinary frequency and urgency. Dallosso and colleagues (2003) found consumption of carbonated drinks to be associated with development of urgency urinary incontinence symptoms. Accordingly, elimination of these dietary irritants may benefit this group. In addition, certain dietary supplements such as calcium glycerophosphate (Prelief) have been shown to decrease urgency and frequency symptoms (Bologna, 2001). This is a phosphate-based product that buffers urine acidity.

Scheduled Voiding

Women with urgency urinary incontinence may feel voiding urges as frequently as every 10 to 15 minutes. Initial goals extend voidings to half-hour intervals. Tools used to achieve this include Kegel exercises during waves of urgency or mental distraction techniques during these times. Scheduled voiding, although used primarily for urgency urinary incontinence, also may be helpful for those with SUI. For these patients, regularly scheduled urination leads to an empty bladder during a greater percentage of the day. Because some women will leak urine only if bladder volumes surpass specific volumes, frequent emptying can significantly decrease incontinence episodes.

Estrogen Replacement

Estrogen has been shown to enhance urethral blood flow and increase α-adrenergic receptor sensitivity. This thereby improves urethral coaptation and urethral closure pressure. Hypothetically, estrogen may also increase collagen deposition and promote vascularity of the periurethral capillary plexus. These also are purported to improve urethral coaptation. Thus, for incontinent women who are atrophic, administration of exogenous estrogen is reasonable.

Estrogen is commonly administered topically, and many different regimens are appropriate. At our institution, we use conjugated equine estrogen cream (Premarin cream) administered twice weekly. Although no data are available to address the duration of treatment, women may be treated chronically with topical estrogen cream. Alternatively, oral estrogen may be prescribed if other menopausal symptoms for which estrogen would be beneficial coexist (Chap. 22, p. 480). However, despite these suggested benefits, a consensus regarding estrogen's beneficial effects on the lower urinary tract has not been reached. Specifically, some studies have shown worsening or development of urinary incontinence with systemic estrogen

administration (Cody, 2012; Grady, 2001; Grodstein, 2004; Hendrix, 2005; Jackson, 2006).

Treatment of Stress Urinary Incontinence

Medications

Pharmaceutical treatment plays a minor role for those with SUI. For women with mixed urinary incontinence, a trial of imipramine can be considered to aid urethral contraction and closure. As discussed, this tricyclic antidepressant has α-adrenergic effects, and the urethra contains a high content of these receptors. However, the efficacy of this pharmacologic intervention may not be substantial, providing only mild symptomatic improvement.

Pessary and Urethral Inserts

Certain pessaries have been designed to treat incontinence and comorbid POP. These "incontinence pessaries" are designed to reduce downward excursion or funneling of the urethrovesical junction (Fig. 24-16, p. 548). This provides bladder neck support and thereby helps reduce incontinence episodes. Pessary use success rates for urinary incontinence vary, depending on the degree of prolapse and other factors. Not all women are appropriate candidates for devices, nor will all desire long-term management of incontinence or prolapse with these.

One large prospective trial compared incontinence pessary use and behavioral therapy for women with SUI (Richter, 2010b). Those using pessary (40 percent) and women completing behavioral therapy (49 percent) were either much or very much improved at 3 months. The women randomly assigned to behavioral therapy reported greater treatment satisfaction, and a higher percentage reported no bothersome incontinence symptoms. An over-the-counter vaginal insert called Impressa is also available to address SUI.

As an alternative to pessaries, urethral occlusive devices include *urethral inserts* (FemSoft; Reliance Urinary Control Insert) and *urethral patches* (CapSure; Re/Stor). Urethral inserts conform to the urethra and create a seal at the bladder neck to prevent accidental leakage. During routine bathroom visits, the insert is removed, discarded, and replaced with a fresh insert. Although data are limited on the effectiveness of inserts, adverse effects of mucosal irritation or superficial bacterial infection are generally minor. In an observational study of 150 women, Sirls and associates (2002) found significantly reduced rates of incontinence episodes with the FemSoft device. With urethral patches, a water-tight seal is created over the urethra after the patch adheres to surrounding periurethral skin using adhesive gel. Similarly, although success rates vary between 44 and 97 percent, these devices are associated with minimal adverse effects (Bellin, 1998; Versi, 1998).

Surgery

For those who are unsatisfied with or do not desire conservative management, surgery may be an appropriate next step for SUI. As noted earlier, urethral support is integral to continence (p. 519). Thus, surgical procedures that recreate this support often diminish or cure incontinence. In general, these surgical procedures are believed to prevent bladder neck and proximal urethra descent during increases in intraabdominal pressure and are grouped as shown in Table 23-4. General postoperative risks for continence surgeries include lower urinary tract injury, uncorrected or recurrent SUI, and creation of de novo voiding dysfunction such as urgency or retention.

TABLE 23-4. Summary of Incontinence Procedures

Procedure	Description	Indication	Comments
Midurethral slings: TVT, TOT	Midurethra supported by mesh placed: by retropubic approach or by transobturator approach	SUI; ISD SUI	Effective short-term treatment, rapid postoperative recovery; TVT with long-term efficacy data; further study required to determine effectiveness of TOT in patients with ISD
Retropubic urethropexy	Periurethral and perivesicular fibromuscular tissue attached to: Cooper ligament (Burch) or symphysis pubis (MMK)	SUI	Effective long-term treatment; requires surgeon experience; less reproducible benefits than midurethral sling procedure
Pubovaginal slings	Bladder neck supported by fascial strip attached to anterior abdominal wall	ISD; failed SUI procedure	Effective long-term treatment; may be useful when synthetic material is not desirable; requires graft isolation
Urethral injection	Bulking agent into urethral submucosa	ISD	Also for SUI in poor surgical candidates; may require several repeated injections
Needle suspension	Proximal urethra suspended by anterior abdominal wall	SUI	Low long-term success rates; no longer recommended for SUI
Paravaginal defect repair	Lateral vaginal wall attached to ATFP	Vaginal prolapse	No longer recommended for SUI

ATFP = arcus tendineus fascia pelvis; ISD = intrinsic sphincteric deficiency; MMK = Marshall-Marchetti-Krantz procedure; SUI = stress urinary incontinence; TOT = transobturator tape; TVT = tension-free vaginal tape.

Midurethral Slings. The therapeutic mechanism of these slings is based on the integral theory hypothesized by Petros and Ulmsten (1993). In brief, control of urethral closure involves the interplay of three structures: the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. Loss of these supports lead to urinary incontinence and pelvic floor dysfunction. Midurethral slings are believed to recreate this structural support.

These procedures vary, but all use a vaginal approach to place synthetic mesh beneath the midurethra. Recovery from midurethral sling placement is rapid, and many gynecologists provide this surgery on an outpatient basis. As such, these are often a popular surgical treatment for SUI. Simplistically, they are classified according to the route of placement and are subdivided into a retropubic or a transobturator approach.

For the retropubic approach, several commercial kits are available, and one commonly used is the tension-free vaginal tape (TVT). With this, the sling (tape) is placed through a vaginal incision to create a hammock beneath the urethra. On each side of the urethra, the sling's arms are brought out to the lower anterior abdominal wall and affixed. For this procedure, sharp trocars traverse the retropubic space as illustrated in Section 45-4 of the atlas (p. 1094). Thus, bladder puncture and retropubic space vessel laceration are specific risks. Many studies attest to this procedure's efficacy (Holmgren, 2005; Song, 2009). One prospective long-term observational study confirmed the long-term safety and efficacy of the TVT device. At 17 years, 87 percent were subjectively cured or significantly improved (Nilsson, 2013).

For the transobturator tape (TOT) approach, various kits are available, and sling material is directed bilaterally through the obturator foramen and underneath the midurethra. The entry point overlies the proximal tendon of the adductor longus muscle of the inner thigh as shown in Section 45-5 (p. 1097). This approach was introduced with the intent to reduce the vascular and lower urinary tract injury risks that can be associated with traversing the retropubic space.

The TOT procedure is indicated for primary SUI secondary to loss of urethral support. Subjective success rates range from 73 to 92 percent up to 5 years after surgery (Abdel-Fattah, 2012; Laurikainen, 2014; Wai, 2013). In patients with SUI secondary to ISD, the value of the TOT approach is unclear as results are conflicting and data are limited (Miller, 2006; O'Connor, 2006; Richter, 2010a).

Although abundant longer-term data regarding the efficacy of TOT approaches are lacking, several intermediate-term studies comparing the two types of midurethral sling procedures suggest similar efficacy with respect to the treatment of urodynamic stress incontinence. One multicenter randomized study of 597 women found no significant differences at 12 months in objective and subjective success rates between the retropubic (81 and 62 percent) and the transobturator (73 and 56 percent) routes, respectively (Richter, 2010a). The retropubic route had a significantly higher rate of postoperative voiding dysfunction that required reoperation, whereas the transobturator route resulted in more neurologic symptoms. Overall quality of life and satisfaction scores with the two procedures were similar. Others have found similar findings with respect to procedure–related complications. Namely, the retropubic route has a higher rate of bladder injury but required a decreased use of anticholinergic medication postoperatively (Barber, 2006; Brubaker, 2011).

Modification of the TVT and TOT procedure is seen with the minimally invasive slings, sometimes called "microslings" or "minislings." With this technique, an 8-cm-long strip of polypropylene synthetic mesh is placed across and beneath the midurethra through a small vaginal incision. Mesh is not threaded through the retropubic space as with TVT, nor does it perforate the obturator membrane as with TOT. That said, lower urinary tract injury is not completely averted with this method. Initial results for the minislings suggested high objective and subjective cure rates (Neuman, 2008). However, in one study, the minisling group had a higher proportion of patients with more severe incontinence 1 year after surgery than those in a retropubic sling group (Barber, 2012).

The Food and Drug Administration (FDA) (2019) has confirmed their update regarding considerations about surgical mesh for SUI. In that statement, the established safety and efficacy of mesh sling procedures for the treatment of SUI were upheld for full-length multiincision operations. They further noted that the safety and effectiveness of minislings had not yet been adequately demonstrated.

Retropubic Urethropexy. Traditionally performed via laparotomy, this group includes the Burch and Marshall-Marchetti-Krantz (MMK) colposuspension procedures. The Burch technique uses the strength of the iliopectineal ligament (Cooper ligament) to lift the anterior vaginal wall and the periurethral and perivesicular fibromuscular tissue. In contrast, during MMK surgery, the periosteum of the symphysis pubis is used to suspend these tissues. Thus, an added risk for MMK is osteitis pubis. However, with the advent of less invasive procedures for SUI, such as the midurethral sling, these techniques are less commonly performed.

Retropubic urethropexy effectively treats SUI. One-year overall continence rates range between 85 and 90 percent, and the 5-year continence rate approximates 70 percent (Lapitan, 2009). As another indication, data suggest that Burch retropubic urethropexy performed concurrently with abdominal sacrocolpopexy (ASC) may significantly reduce rates of later, postoperative de novo SUI (Chap. 24, p. 554) (Brubaker, 2008a). In support of this practice, a 7-year follow-up study showed that patients undergoing ASC and prophylactic Burch urethropexy still demonstrated lower de novo SUI rates than women receiving ASC alone (Nygaard, 2013).

Pubovaginal Slings. With this surgery, a strip of either rectus fascia or fascia lata is placed under the bladder neck and through the retropubic space. The ends are secured at the level of the rectus abdominis fascia (Section 45-6, p. 1099). This surgery has traditionally been used for SUI stemming from ISD. In addition, this procedure may also be indicated for patients with prior failed continence operations. Last, concern for potential mesh complications with surgery for incontinence and pelvic floor reconstruction has re-stimulated interest in the Burch and pubovaginal sling procedures.

Urethral Bulking Agent Injection. Using cystoscopic guidance, agents can be injected into the urethral submucosa to "bulk

up" the mucosa and improve coaptation. Surgical steps and agent types are described in Section 45-7 (p. 1101). This option has traditionally been indicated for women who have stress incontinence associated with ISD. However, the FDA has broadened criteria for their use to include patients with less severe leak point pressures. Thus, those with leak point pressures <100 cmH_2O also may be candidates (McGuire, 2006). Additionally, this office procedure is a useful alternative for women with SUI who have multiple medical problems and are thus poor surgical candidates.

Transvaginal Needle Procedures and Paravaginal Defect Repair. In the 1960s through 1980s, needle suspension procedures such as the Raz, Pereyra, and Stamey techniques were popular operations for SUI but have now largely been replaced by other methods. In brief, these surgeries use specially designed ligature carriers to place sutures through the anterior vaginal wall and/or periurethral tissues and suspend them to various levels of the anterior abdominal wall. These rely on the strength and integrity of the periurethral tissue and abdominal wall strength to correct urethral hypermobility and prevent bladder neck and proximal urethra descent. Although initial cure rates are satisfactory, the durability of these procedures wanes with time. Success rates range from 50 to 60 percent, well below rates found with other current continence procedures (Moser, 2006). Failure stems largely from "pull-through" of sutures at the level of the anterior vaginal wall.

In addition, abdominal paravaginal defect repair (PVDR) is a surgical procedure that corrects lateral support defects of the anterior vaginal wall. The technique involves suture attachment of the lateral vaginal wall to the arcus tendineus fascia pelvis. Currently, PVDR is primarily a prolapse-correcting operation. Although previously used to correct SUI, long-term data show this to no longer be a superior method for primary treatment of SUI (Colombo, 1996; Mallipeddi, 2001).

Treatment of Urgency Urinary Incontinence

Anticholinergic Medications

These medications appear to work at the level of the detrusor muscle by competitively inhibiting acetylcholine at muscarinic receptors (M_2 and M_3) (Miller, 2005). These agents thereby blunt detrusor contractions to reduce the number of incontinence episodes and volume lost with each. These medications are significantly better than placebo at improving symptoms of urgency urinary incontinence and overactive bladder. However, in one systematic review, the reduction in baseline urgency incontinence episodes per day reflected only a modest benefit (Nabi, 2006).

Oxybutynin, Tolterodine, and Fesoterodine. These frequently used drugs competitively bind to cholinergic receptors (Table 23-5). As noted, muscarinic receptors are not limited

TABLE 23-5. Pharmacologic Treatment of Overactive Bladder

Drug Name	Brand Name	Drug Type	Dosage[a]	Available Doses
Oxybutynin (short-acting)	Ditropan	Antimuscarinic	2.5–5 mg three times daily	5-mg tablet, 5-mg/mL syrup
Oxybutynin (long-acting)	Ditropan XL	See above	5–30 mg daily	5-, 10-, 15-mg tablet
Oxybutynin (transdermal)	Oxytrol	See above	3.9 mg/d; change patch twice weekly	36-mg patch, 8 per carton
Oxybutynin (transdermal) 10% gel	Gelnique	See above	Gel apply 1 g daily	1-g packet, 30 per carton 1-g pump dose, 30 doses per bottle
Tolterodine (short-acting)	Detrol	See above	1–2 mg twice daily	1-, 2-mg tablet
Tolterodine (long-acting)	Detrol LA	See above	2–4 mg daily	2-, 4-mg capsule
Fesoterodine fumarate	Toviaz	See above	4–8 mg daily	4-, 8-mg tablets
Trospium chloride	Sanctura	Antimuscarinic quaternary amine	20 mg twice daily	20-mg tablet
Trospium chloride	Sanctura XR	See above	60 mg daily	60-mg tablet
Darifenacin	Enablex	M_3-selective antimuscarinic	7.5–15 mg daily	7.5-, 15-mg tablet
Solifenacin	Vesicare	M_3-selective antimuscarinic	5–10 mg daily	5-, 10-mg tablets
Imipramine hydrochloride	Tofranil	Tricyclic antidepressant, anticholinergic, α-adrenergic, antihistamine	10–25 mg one to four times daily. Begin with 10–25 mg nightly.	10-, 25-, 50-mg tablets
Mirabegron	Myrbetriq	β_3 adrenergic agonist	25–50 mg daily	25-, 50-mg tablets

[a]Oral dosing except for transdermal forms.

TABLE 23-6. Potential Anticholinergic Side Effects

Side Effect	Potential Clinical Consequence
Increased pupil size	Photophobia
Decreased visual accommodation	Blurred vision
Decreased salivation	Gingival and buccal ulceration
Decreased bronchial secretions	Small-airway mucus plugging
Decreased sweating	Hyperthermia
Increased heart rate	Angina, myocardial infarction
Decreased detrusor function	Bladder distention and urinary retention
Decreased gastrointestinal mobility	Constipation

to the bladder. Thus, drug side effects may be significant. Of these, dry mouth, constipation, and blurry vision are common, and dry mouth is a primary reason for drug discontinuation (Table 23-6). Importantly, anticholinergics are contraindicated in those with narrow-angle glaucoma.

Because of these side effects, the therapeutic goal of bladder M_3 blockade with these antimuscarinic agents is often limited. Thus, drug selection is tailored, and efficacy is balanced against tolerability. For example, Diokno and associates (2003) found oxybutynin to be more effective than tolterodine. However, tolterodine was associated with lower side effect rates. Tolterodine and fesoterodine have also been compared in a randomized study of 1135 patients. Fesoterodine was found to perform better than tolterodine, although once again, side effects were lowest in the tolterodine group (Chapple, 2008). A population-based study reported that only 56 percent of women felt their overactive bladder medication was effective, and half discontinued it (Diokno, 2006).

Most side effects attributed to oxybutynin stem from its secondary metabolite that follows liver metabolism. Therefore, to minimize oral oxybutynin side effects, a transdermal patch was designed to lower liver metabolism and the "first-pass" effect of this drug. Dmochowski and coworkers (2003) found fewer anticholinergic side effects with transdermal oxybutynin compared with long-acting oral tolterodine.

Transdermal oxybutynin is supplied as a 7.6 × 5.7 cm patch that is applied to the abdomen, hip, or buttock; worn continuously; and changed twice weekly. Each patch contains 36 mg of oxybutynin and delivers approximately 3.9 mg daily. Application-site pruritus is the most frequent side effect, and varying the application site may minimize skin reactions (Sand, 2007). A transdermal 3-percent oxybutynin gel is applied daily to skin of the abdomen, upper arms/shoulders, or thigh, and application sites are rotated.

Imipramine. This agent is less effective than tolterodine and oxybutynin but displays α-adrenergic and anticholinergic characteristics. Therefore, it is occasionally prescribed for those with mixed urinary incontinence. Importantly, doses of imipramine used to treat incontinence are significantly lower than those used to treat depression or chronic pain. In our experience, this minimizes the theoretical risk of drug-related side effects.

Selective Muscarinic-Receptor Antagonists. These anticholinergic medications were introduced with the aim of reducing side effects. The agents are all M_3-receptor selective antagonists and include solifenacin, trospium chloride, and darifenacin. Earlier urgency warning time and fewer muscarinic side effects have been shown in randomized studies (Cardozo, 2004; Chapple, 2005; Haab, 2006; Zinner, 2004). However, although the side-effect profiles of these drugs are potentially more attractive, they have not been proven superior in efficacy to nonselective muscarinic agents (Hartmann, 2009).

Mirabegron

This is a β_3-adrenergic–receptor agonist for the treatment of urgency urinary incontinence, urgency, and frequency. Activation of these receptors results in relaxation of the detrusor smooth muscle and greater bladder capacity. Most commonly reported adverse reactions include hypertension, nasopharyngitis, UTIs, dry mouth, and headache (Herschorn, 2013). Mirabegron is contraindicated in patients with severe uncontrolled hypertension (systolic blood pressure ≥180 mm Hg or diastolic blood pressure ≥110 mm Hg, or both).

Sacral Neuromodulation

Urine storage and bladder emptying require a complex coordinated interaction of spinal cord and higher brain centers, peripheral nerves, urethral and pelvic floor muscles, and the detrusor muscle. If any of these levels are altered, normal micturition is lost. To overcome these problems, electrical nerve stimulation, also called *neuromodulation*, has been used. InterStim is the only implantable neuromodulation system approved by the FDA for treatment of refractory urgency urinary incontinence and for treatment of anal incontinence. It may be also considered for those with pelvic pain, IC/BPS, and defecatory dysfunction, although it is not FDA-approved for these indications. Sacral neuromodulation is not considered primary therapy and is typically offered mainly to women who have exhausted pharmacologic and conservative options.

This outpatient surgically implanted device contains a pulse generator, which is connected to electrical leads that are placed into the sacral foramina. Here, it acts to modulate bladder and pelvic floor innervation. Although incompletely understood, it promotes somatic afferent inhibition that interrupts abnormal reflex arcs in the sacral spinal cord involved in the filling and evacuation phases of micturition.

Implantation is typically a two-stage process. Initially, leads are placed and attached to an externally worn generator (Section 45-12, p. 1111). After placement, frequency and amplitude of electrical impulses can be adjusted and tailored to maximize effectiveness. If a 50-percent or greater improvement in symptoms is noted, internal implantation of a permanent pulse generator is planned. This minimally invasive procedure is typically completed in a day-surgery setting. Rare complications are pain or infection at the generator insertion site.

Although its use is often reserved for those who have been unsuccessfully treated with behavioral or pharmacologic therapy, this modality is effective for urinary symptom treatment. In

studies, improvement rates range from 60 to 75 percent, and cure rates approximate 45 percent (Janknegt, 2001; Schmidt, 1999; Siegel, 2000). Long-term follow-up shows sustained improvement from baseline incontinence parameters. One 3-year study reported a 57-percent reduction in incontinence episodes per day, and similar findings were found in a separate 5-year study (Kerrebroeck, 2007; Siegel, 2000). A systematic review of 17 case series at follow-up periods of 3 to 5 years similarly reported 39 percent of patients cured and 67 percent with >50-percent improvement in incontinence symptoms (Brazzelli, 2006).

Percutaneous Tibial Nerve Stimulation

Sometimes referred to as *posterior tibial nerve stimulation*, percutaneous tibial nerve stimulation (PTNS) is becoming a more common therapy for refractory urgency urinary incontinence. It involves percutaneous needle electrode placement into an area cephalic to the medial malleolus of the lower extremity. Electrical pulses are sent via a generator to the tibial nerve. This nerve originates from spinal roots L4–S3, and its stimulation leads to retrograde neuromodulation. Multicenter studies have demonstrated its efficacy compared with sham or with primary treatment with anticholinergic medication (Peters, 2009, 2010; MacDiarmid, 2010).

Botulinum Toxin A

Injection of botulinum toxin A (onabotulinumtoxinA) into the bladder wall is approved for the treatment of idiopathic detrusor overactivity. Three placebo-controlled studies showed the effectiveness of this treatment (Anger, 2010). All three used cystoscopic injection of 200 units of botulinum toxin A toxin or placebo, and each demonstrated significantly improved incontinence. Improvement occurred as early as 4 weeks after injection (Brubaker, 2008b; Flynn, 2009; Khan, 2010; Sahai, 2007). Urinary retention—defined as a postvoid residual volume measuring >200 mL—is a common side effect and developed in 27 to 43 percent of patients in these randomized trials. Most patients are asymptomatic, but patients receiving botulinum toxin A for overactive bladder or urgency urinary incontinence are counseled that temporary self-catheterization may be required after injection. More commonly, 100 units of botulinum toxin A is injected, and retention rates are lower.

A patient can expect the effects of the toxin to wane over time. In a small study describing the need for repeat injections, 20 patients from a cohort of 34 received a second injection, and nine patients received up to four injections. These repeat injections appear to be equally effective as the primary injection. Median time between injections approximates 377 days (Sahai, 2010).

One randomized trial compared oral anticholinergic therapy and botulinum toxin A injection in women with idiopathic urgency urinary incontinence. Comparable reductions in incontinence episodes were found. The botulinum toxin A group was less likely complain of dry mouth and more likely to have complete resolution of urgency urinary incontinence (Visco, 2012). Another study comparing botulinum toxin A (200 units) to sacral neuromodulation in a population of women with refractory urgency urinary incontinence found that women in the botulinum toxin A group had a modestly greater reduction in mean number of urgency incontinence episodes per day at 6 months. They also reported greater improvement in symptom bother, treatment satisfaction, and endorsement of treatment. Conversely, the botulinum toxin A patients had a greater number of UTIs (35 percent) compared with sacral neuromodulation (11 percent) (Amundsen, 2016).

CHAPTER 24

Pelvic Organ Prolapse

EPIDEMIOLOGY 536
RISK FACTORS 536
DESCRIPTION AND CLASSIFICATION 537
PATHOPHYSIOLOGY 539
PATIENT EVALUATION 541
NONSURGICAL TREATMENT 547
SURGICAL TREATMENT 550
REFERENCES 555

Pelvic organ prolapse (POP) is a common condition that can lead to urogenital tract dysfunction and diminished quality of life. *Signs* include descent of one or more of the following: the anterior vaginal wall, posterior vaginal wall, uterus and cervix, vaginal apex, or the perineum (Haylen, 2010). *Symptoms* include the sensation of a vaginal bulge, pelvic pressure, and pelvic organ descent. Some degree of POP is present in a large proportion of the female population (Swift, 2000). It is considered a disease state only if surgical or nonsurgical reduction relieves the symptoms, restores function, and improves quality of life.

EPIDEMIOLOGY

POP affects millions of women worldwide. In the United States, it is the third most frequent indication for hysterectomy, and in women older than 70 years, prolapse repair is the most common inpatient procedure (Oliphant, 2010). A woman has a 12- to 19-percent cumulative lifetime risk to undergo POP-corrective surgery (Smith, 2010; Wu, 2014). Considering most women with POP do not elect surgical treatment, these percentages underestimate its true prevalence. Disease estimates are also hampered by inconsistent definitions. If examination alone is used to describe pelvic organ support, 30 to 65 percent of women presenting for routine gynecologic care have stage 2 prolapse (Bland, 1999; Swift, 2000, 2005; Trowbridge, 2008). In contrast, with POP defined solely by patient symptoms, prevalence rates range from 3 to 6 percent in the United States (Bradley, 2005; Nygaard, 2008; Rortveit, 2007). As the population ages, the number of women with POP is expected to rise dramatically, with 9.2 million women predicted to be affected in 2050 (Wu, 2009).

RISK FACTORS

Obstetrics-Related Risks

Table 24-1 summarizes predisposing factors for POP. It usually develops gradually over a span of years, and its etiology is multifactorial. The relative importance, however, of each factor is unknown.

Vaginal childbirth is the risk factor most commonly associated with POP. Some evidence suggests that pregnancy itself predisposes to POP. However, in numerous studies, vaginal delivery is linked to a woman's propensity for developing POP. In the Pelvic Organ Support Study (POSST), the risk of POP rose 1.2 times with each vaginal delivery (Swift, 2005). Compared with nulliparas, Rortveit and colleagues (2007) found that the prolapse risk grew significantly with rising parity in woman with one, two, or three or more vaginal deliveries. In a longitudinal study of 1011 women, vaginal delivery compared with cesarean delivery without labor was associated with a significantly greater risk of vaginal prolapse to the hymen or beyond (Handa, 2011). Last, in a large prospective cohort followed for 17 years, the risk of hospital admission for POP rose fourfold with one delivery and eightfold with two deliveries (Mant, 1997).

Although vaginal delivery is implicated in a woman's lifetime risk for POP, specific obstetric risk factors remain controversial. These include fetal macrosomia, prolonged second-stage labor, episiotomy, anal sphincter laceration, epidural analgesia, forceps use, and oxytocin stimulation of labor. The individual influence of each is yet to be defined.

TABLE 24-1. Risk Factors Associated with Pelvic Organ Prolapse

Pregnancy
Vaginal childbirth
Menopause
Aging
Hypoestrogenism
Chronically increased intraabdominal pressure
Chronic obstructive pulmonary disease
Constipation
Obesity
Pelvic floor trauma
Genetic factors
Race
Connective tissue disorders
Spina bifida

Currently, two obstetric interventions—elective forceps delivery to shorten second-stage labor and elective episiotomy—are not advocated. Both lack evidence of benefit and carry risks for maternal and fetal harm. First, forceps delivery is directly implicated in pelvic floor injury through its association with anal sphincter laceration and levator ani muscle avulsion. In one study of pelvic floor anatomy at a median of 11 years postdelivery, 45 percent of all levator ani muscle avulsion lesions were sonographically identified in women with prior forceps delivery. In those with recognized avulsion, prolapse beyond the hymen was more prevalent (Handa, 2019). Overall, evidence suggests that operative vaginal birth raises the odds for POP sevenfold (Handa, 2011). For these reasons, elective forceps delivery is not recommended solely to prevent pelvic floor disorders. Likewise, at least twelve randomized trials comparing elective and selective episiotomy for women not undergoing operative vaginal delivery found no benefit from routine episiotomy. Instead, an association with anal sphincter laceration, postpartum anal incontinence, and postpartum pain was identified (Jiang, 2017).

Elective cesarean delivery to prevent pelvic floor disorders such as POP and urinary incontinence is controversial. In one large study of women followed 5 to 10 years after a first delivery, the POP risk in women who delivered vaginally was five times higher than that in those who underwent cesarean delivery without labor (Handa, 2011). Theoretically, if all women underwent cesarean delivery, fewer women would have POP. However, most women do not have symptomatic POP. Thus, cesarean delivery on maternal request (CDMR) with the goal of POP prevention would subject many women who would otherwise not develop the problem to a potentially dangerous intervention. Specifically, given the 11-percent lifetime risk for POP or incontinence surgery, for every one woman who would avoid pelvic floor surgery later in life by undergoing primary elective cesarean delivery, nine women would gain no benefit yet would nevertheless assume the potential risks of the cesarean (Patel, 2006). Currently, decisions regarding CDMR to prevent pelvic floor disorders must be individualized. The American College of Obstetricians and Gynecologists (2019a) recommends vaginal delivery as safe and appropriate in the absence of recognized maternal or fetal indications for cesarean delivery. The opinion does not address POP risk as a cesarean delivery indication and cites poor-quality evidence.

Age

Data from several studies show that POP prevalence rises steadily with aging (Nygaard, 2008; Olsen, 1997; Swift, 2005). In the POSST study, in women aged 20 to 59 years, the POP incidence roughly doubled with each decade. Aging is a complex process, and separating the effects of physiologic aging and estrogen deprivation is problematic. Reproductive hormones are essential to maintain pelvic organ support, and their specific effects on pelvic support are outlined earlier (Chap. 22, p. 499).

Connective Tissue Disease

Women with connective tissue disorders may be more likely to develop POP. In a small case series, one third of women with Marfan syndrome and three fourths of those with Ehlers-Danlos syndrome reported a history of POP (Carley, 2000).

Race

POP prevalence varies by race (Schaffer, 2005). Black and Asian women show the lowest risk, whereas Hispanic and white women appear to have the highest (Hendrix, 2002; Kim, 2005; Whitcomb, 2009). Differences may derive from variable collagen content or bony pelvis shape. For instance, black women more commonly have a narrow pubic arch and an android or anthropoid pelvis. These shapes protect against POP compared with the gynecoid pelvis typical of most white women.

Intraabdominal Pressure

Elevated intraabdominal pressure from chronic constipation, chronic coughing, repetitive heavy lifting, and obesity may contribute to POP pathogenesis. In the Women's Health Initiative trial, being overweight increased the POP rate by 31 to 39 percent, and being obese raised the POP rate by 40 to 75 percent (Hendrix, 2002). Similarly, overweight and obese women were 40 to 50 percent more likely to have POP compared with normal-weight women in one metaanalysis (Giri, 2017).

With regard to lifting, Danish nursing assistants who were involved with repetitive heavy lifting had a higher rate of surgical intervention for POP compared with the general population rate (Jorgensen, 1994). Similarly, in another study, laborers had greater rates of severe POP than those with sedentary jobs (Woodman, 2006).

Cigarette smoking and chronic obstructive pulmonary disease (COPD) also are implicated in POP development (Gilpin, 1989; Olsen, 1997). In one case-control study, COPD was associated with an increased risk of future pelvic floor repair after hysterectomy (Blandon, 2009). The repetitive elevations in intraabdominal pressure resulting from chronic coughing may predispose to POP. Also, rather than the cough itself, inhaled tobacco chemicals may cause connective tissue changes that lead to POP (Wieslander, 2005).

Genetic Factors

Ongoing studies suggest a genetic basis for POP (Ward, 2014). Some studies show a fivefold higher rate of POP among siblings with severe POP compared to the general population (Jack, 2006). Likewise, concordance of POP in twins and in sister pairs is significant (Altman, 2008). Moreover, recent genome-wide linkage studies have identified specific predisposition genes (Allen-Brady, 2015). Future investigations may allow better genetic risk stratification, patient counseling, and prevention strategies.

DESCRIPTION AND CLASSIFICATION

Visual Descriptors

POP is descent of the anterior vaginal wall, posterior vaginal wall, uterus (cervix), the vaginal apex after hysterectomy, rectum, or the perineum, alone or in combination. The terms *cystocele*, *rectocele*, and *enterocele* have traditionally described the structures thought to be prolapsed behind the vaginal wall. However, these terms are imprecise and misleading, as they focus on what is presumed to be prolapsed rather than what is objectively seen to

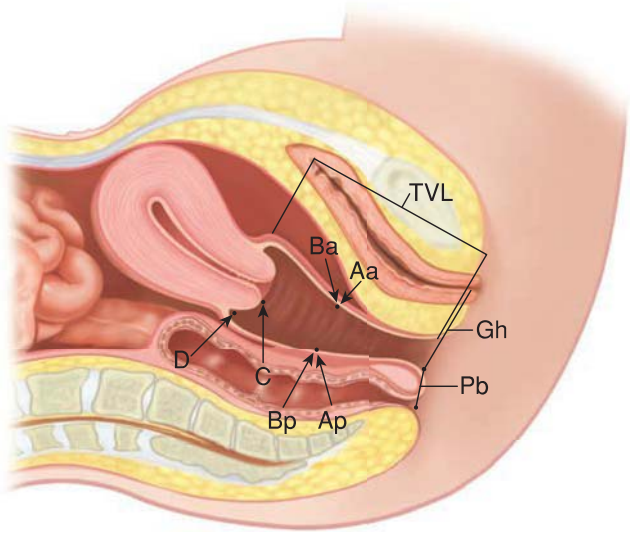

FIGURE 24-1 Anatomic landmarks used during pelvic organ prolapse quantification (POP-Q).

be prolapsed. Current preferred terms are *anterior vaginal wall prolapse*, *apical prolapse*, *cervical prolapse*, *posterior vaginal wall prolapse*, *rectal prolapse*, and *perineal descent*.

Pelvic Organ Prolapse Quantification

In 1996, the International Continence Society defined a system of Pelvic Organ Prolapse Quantification (POP-Q) (Bump, 1996). Demonstrating high intra- and interexaminer reliability, the POP-Q system measures the site-specific components of pelvic organ support. Prolapse in each segment is measured relative to the hymen, which is an anatomic landmark that can be identified consistently. The numeric measurement is assigned a negative sign if the prolapsed point is proximal to the hymen or is given a positive sign if it protrudes past the hymen. Six points are located with reference to the hymeneal plane: two on the anterior vaginal wall (points Aa and Ba), two at the vaginal apex (points C and D), and two on the posterior vaginal wall (points Ap and Bp) (Fig. 24-1). The genital hiatus (Gh), perineal body (Pb), and total vaginal length (TVL) are also measured. All POP-Q points, except TVL, are measured during patient Valsalva and should reflect maximum protrusion.

The POP-Q measurements can be organized using a three-by-three grid shown in Figure 24-2. Figures 24-3 and 24-4 illustrate the use of POP-Q in evaluating different examples of POP (Bump, 1996).

The degree of prolapse can also be quantified using a five-stage ordinal system summarized in Table 24-2 (Bump, 1996). Stages are assigned according to the most severe portion of the prolapse. Used in the past and now less preferred, the Baden-Walker Halfway system uses a grading system to define POP. Normal organ positioning is grade 0, whereas organ descent that is half the distance to the hymen, at the hymen, or maximally prolapsed are grades 1, 2, and 3, respectively (Baden, 1992).

anterior wall **Aa**	anterior wall **Ba**	cervix or cuff **C**
genital hiatus **gh**	perineal body **pb**	total vaginal length **tvl**
posterior wall **Ap**	posterior wall **Bp**	posterior fornix **D**

FIGURE 24-2 Grid system used for charting in pelvic organ prolapse quantification (POP-Q).

Vaginal Apex Points

With POP-Q assessment, the two apical points, C and D, which are located in the proximal vagina, represent the most

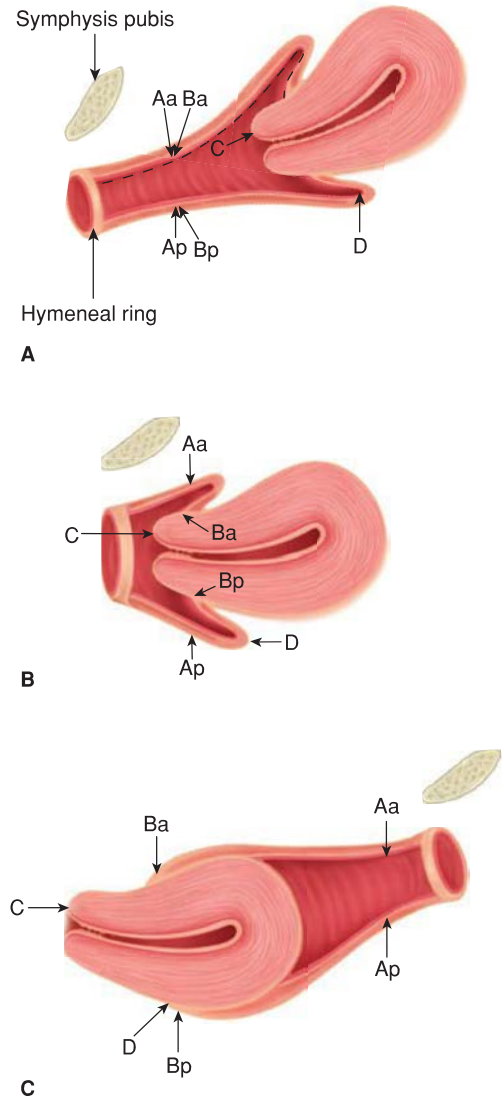

FIGURE 24-3 POP-Q depiction of varying degrees of uterine prolapse. **A.** Stage 0. **B.** Stage 2. **C.** Stage 4.

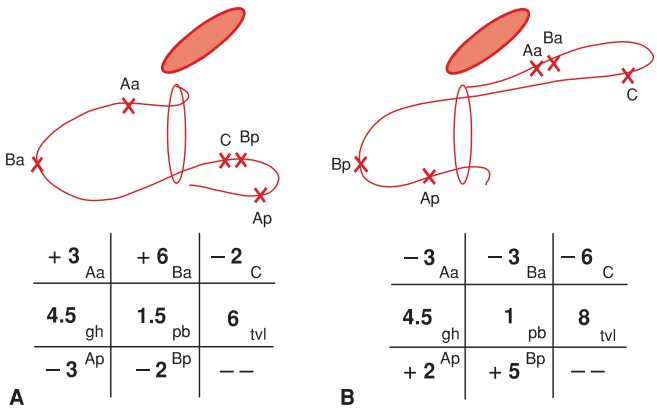

FIGURE 24-4 Grid and drawing of an anterior support defect (**A**) and posterior support defect (**B**).

cephalad locations of the vagina. Point C defines a point that reflects: (1) the most distal edge of the cervix or (2) the leading edge of the vaginal cuff after total hysterectomy. Point D defines a point that represents the posterior fornix in a woman who still has a cervix. It is omitted in the absence of a cervix. This point represents the level of uterosacral ligament attachment to the cervix and thus differentiates uterosacral ligament support failure from cervical elongation. The TVL is the greatest depth of the vagina in centimeters when point C or D is reduced to its fullest position.

Genital Hiatus and Perineal Body

The genital hiatus is measured from the middle of the external urethral meatus to the midline of the posterior hymeneal ring. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening (see Fig. 24-1).

Anterior Vaginal Wall Points

Point Aa defines a point that lies in the midline of the anterior vaginal wall and is 3 cm proximal to the external urethral meatus. This corresponds to the proximal location of the urethrovesical crease. In relation to the hymen, this point's position ranges from –3 (normal support) to +3 cm (maximum prolapse of point Aa).

Point Ba represents the most distal position of any part of the upper anterior vaginal wall, that is, the segment of vagina that normally would lie cephalad from point Aa. It is –3 cm in the absence of prolapse. In a woman with total vaginal eversion post-hysterectomy, Ba would have a positive value equal to the position of the cuff from the hymen.

Posterior Vaginal Wall Points

Point Ap defines a point in the midline of the posterior vaginal wall that lies 3 cm proximal to the hymen. Relative to the hymen, this point's range of position is by definition –3 (normal support) to +3 cm (maximum prolapse of point Ap).

Point Bp represents the most distal position of any part of the upper posterior vaginal wall. By definition, this point is at –3 cm in the absence of prolapse. In a woman with total post-hysterectomy vaginal vault eversion, Bp would have a positive value equal to the position of the cuff from the hymen.

PATHOPHYSIOLOGY

Levator Ani Muscle

Pelvic organ support is maintained by complex interactions among the pelvic floor muscles, pelvic floor connective tissue, and vaginal wall. These work in concert to provide support to and aid function of the vagina, urethra, bladder, and rectum.

The levator ani muscle is a pair of striated muscles composed of three regions, which are the *iliococcygeus muscle*, *pubococcygeus muscle*, and *puborectalis muscle*. These are illustrated in Chapter 38 (p. 798). Connective tissue covers the superior and inferior fascia of the levator ani muscle. Normally, its baseline resting contraction elevates the pelvic floor and compresses the vagina, urethra, and rectum toward the pubic bone (Fig. 38-10, p. 800). This narrows the genital hiatus and prevents POP. In addition, the upper vagina normally lies nearly horizontal

TABLE 24-2. The Pelvic Organ Prolapse Quantification (POP-Q) Staging System of Pelvic Organ Support

Stage 0:	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at –3 cm and either point C or D is between –TVL (total vaginal length) cm and –(TVL–2) cm (i.e., the quantitation value for point C or D is ≤–[TVL–2] cm). Fig. 24-1 represents stage 0
Stage I:	The criteria for stage 0 are not met, but the most distal portion of the prolapse is >1 cm above the level of the hymen (i.e., its quantitation value is <–1 cm)
Stage II:	The most distal portion of the prolapse is ≤1 cm proximal to or distal to the plane of the hymen (i.e., its quantitation value is ≥–1 cm but ≤+1 cm)
Stage III:	The most distal portion of the prolapse is >1 cm below the plane of the hymen but protrudes no further than 2 cm less than the total vaginal length in centimeters (i.e., its quantitation value is >+1 cm but <+[TVL–2] cm). Fig. 24-4A represents stage III Ba and Fig. 24-4B represents stage III Bp prolapse
Stage IV:	Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (TVL–2) cm (i.e., its quantitation value is ≥+[TVL–2] cm). In most instances, the leading edge of stage IV prolapse will be the cervix or vaginal cuff scar. Fig. 24-3C represents stage IV C prolapse

From Bump, 1996, with permission.

in the standing female. Thus, during periods of greater intraabdominal pressure, the upper vagina is compressed against the levator plate. One theory suggests that lost levator ani muscle tone allows the vagina to drop from a horizontal position to a semivertical one (Fig. 38-11, p. 800). This widens the genital hiatus, and the pelvic viscera are thereby predisposed to prolapse. Moreover, without adequate levator ani muscle support, visceral fascial attachments of the pelvic contents are placed on tension. These attachments stretch over time and eventually fail.

Loss of skeletal muscle volume and function develops in virtually all striated muscles during aging. Results obtained from young and older women with POP indicate that the levator ani muscle undergoes substantial morphologic and biochemical changes with time. Thus, loss of levator tone with age may contribute to pelvic organ support failure in older women, especially those with preexisting defects in connective tissue support.

Another hypothesis suggests that levator ani muscle tone may be lost following denervation. During second-stage labor, nerve injury can result from stretch or compression or both (DeLancey, 1993; Peschers, 1997; Shafik, 2000). Experimental evidence for this theory has been difficult to obtain and is contradictory (Boreham, 2009; Gilpin, 1989; Hanzal, 1993; Heit, 1996; Koelbl, 1989). In sum, denervation-induced injury is not currently implicated in POP genesis.

Connective Tissue

A continuous interdependent system of connective tissues and ligaments surrounds the pelvic organs and attaches them to the levator ani muscle and bony pelvis. Comprised of collagen, elastin, smooth muscle, and microfibers, this connective tissue network provides substantial pelvic organ support.

One component is the *arcus tendineus fascia pelvis*. It is a condensation of parietal fascia covering the medial aspects of the obturator internus and levator ani muscle (Fig. 38-7, p. 797). It provides the lateral and apical anchor sites for the anterior and posterior vagina. The arcus tendineus fascia pelvis is thus poised to withstand downward pressures against the anterior vaginal wall, vaginal apex, and proximal urethra. In one theory, loss of vaginal apex support leads to stretching or tearing of the arcus tendineus fascia pelvis. The result is apical and anterior vaginal wall prolapse.

The *uterosacral ligaments* also contribute to apical support by suspending and stabilizing the uterus, cervix, and upper vagina. The ligament contains approximately 20 percent smooth muscle. In women with prolapse, smooth muscle content in the uterosacral ligaments is diminished (Reisenauer, 2008; Takacs, 2009).

The muscular and connective tissue support of the pelvic floor is estrogen responsive, and estrogen deficiency can diminish the quality and quantity of collagen. Specifically, estrogen and progesterone receptors are identified in the connective tissue and smooth-muscle cells of both the levator ani muscle and uterosacral ligaments (Smith, 1990, 1993). In histologic studies, the ratio of collagen I to collagen III and IV is decreased in postmenopausal women not using estrogen therapy (Moalli, 2004). This relative decline in well-organized, dense collagen is believed to weaken vaginal wall tensile strength and raise vaginal wall prolapse susceptibility. Rahn and coworkers (2014) found that vaginal estrogen application before POP surgery improved the vaginal maturation index, enhanced synthesis of mature collagen, and increased vaginal epithelial thickness. This suggests a possible role in healing and postsurgical support. Indeed, estrogen supplementation before or after prolapse surgery is considered essential by many pelvic reconstruction surgeons. Although this practice is empirically sound, evidence is yet to show improved surgical outcomes with this use of adjuvant estrogen.

Last, abnormalities of connective tissue and connective tissue repair may predispose women to POP (Norton, 1995; Smith, 1989). As noted, women with Ehlers-Danlos or Marfan syndrome are more likely to develop POP and urinary incontinence (Carley, 2000; Norton, 1995).

Vaginal Wall

The vaginal wall and its attachments to the pelvic floor muscles are integral to pelvic organ support. The vaginal wall is composed of mucosa (epithelium and lamina propria), a muscularis layer, and an adventitial layer that is made up of loose areolar tissue, abundant elastic fibers, and neurovascular bundles (Fig. 24-5). The muscularis and adventitial layers together form the *fibromuscular layer*, which was previously referred to as "endopelvic fascia." The fibromuscular layer coalesces laterally and attaches to the arcus tendineus fascia pelvis and superior fascia of the levator ani muscle. In the lower third of the vagina, the vaginal wall is attached directly to the perineal membrane and the perineal body. This suspensory system, together with the uterosacral ligaments, prevents vaginal and uterine descent.

Thus, abnormalities in the anatomy, physiology, and cellular biology of vaginal wall smooth muscle may contribute to POP. Specifically, in fibromuscular tissue taken from vaginal walls at the apex, prolapse is associated with loss of smooth muscle, myofibroblast activation, abnormal smooth muscle phenotype, and enhanced protease activity (Boreham, 2001, 2002a,b; Moalli, 2005; Phillips, 2006). Abnormal synthesis or degradation of

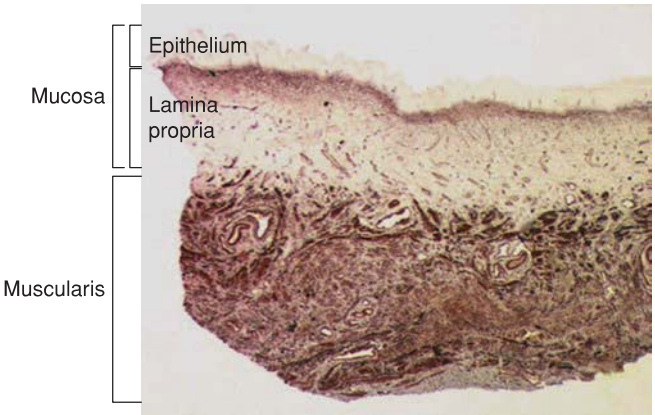

FIGURE 24-5 Photomicrograph shows a cross section of the vaginal wall. Mucosal and muscularis layers are shown here. The adventitia, which is typically seen deep to muscularis, is not shown in this section. The fibromuscular layer is comprised of muscularis and adventitial layers. FIGURE 24-6 Midline or distension anterior vaginal wall defect. Note the characteristic loss of vaginal wall rugae.

vaginal wall collagen and elastin fibers also appears to contribute to POP.

The Defect Theory of Pelvic Organ Prolapse

This theory states that tears in the fibromuscular connective tissue of the vaginal wall allow pelvic organ herniation. For example, weakness, attenuation, or tearing of the vaginal wall in the midline but without loss of lateral fascial attachments is called a *distention* or *midline* anterior vaginal wall defect (Fig. 24-6). With this defect, the vaginal wall appears smooth and without rugae, due to abdominal contents pressed against the vagina from within. In contrast, an anterior wall flaw due to connective tissue detachment of the lateral vaginal wall to the pelvic sidewall is described as a *displacement* or *paravaginal* anterior vaginal wall defect (Fig. 24-7). With displacement-type prolapse, vaginal rugae are visible. Other defects include analogous midline and lateral defects in the posterior vaginal wall, loss of apical support, and defects at the level of the perineal body.

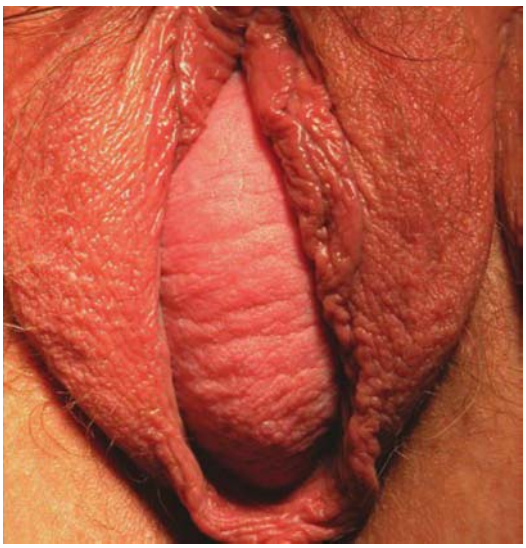

FIGURE 24-7 Lateral anterior vaginal wall defect, also termed paravaginal or displacement anterior vaginal wall defect. Rugae are present, which indicates that loss of support is lateral rather than central.

Many experts believe that loss of support at the vaginal apex is the most important factor in the development of POP. This loss allows the apical portions of the anterior and posterior vaginal walls to descend. As such, resuspension of the vaginal apex will restore support to both these.

Levels of Vaginal Support

DeLancey (1992) has described three levels of vaginal support. Level I support suspends the upper or proximal vagina. Level II support attaches the midvagina along its length to the arcus tendineus fascia pelvis. Level III support results from fusion of the distal vagina to adjacent structures. Defects in each level of support result in identifiable vaginal wall prolapse.

Level I support is the attachment of the cardinal and uterosacral ligaments to the cervix and upper vagina (Fig. 38-15, p. 804). The cardinal ligaments fan out laterally and attach to the parietal fascia of the obturator internus and piriformis muscles, the anterior border of the greater sciatic foramen, and the ischial spines. The uterosacral ligaments are posterior fibers that attach to the presacral region at the level of S2 through S4. Together, this dense visceral connective tissue complex maintains vaginal length and horizontal axis. It allows the vagina to be supported by the levator plate and positions the cervix just superior to the level of the ischial spines. Defects in this support complex can lead to apical prolapse. This is frequently associated with small bowel herniation into the vaginal wall, that is, enterocele.

Level II support consists of the paravaginal attachments that are contiguous with the cardinal/uterosacral complex at the ischial spine. These are the connective tissue attachments of the lateral vagina anteriorly to the arcus tendineus fascia pelvis and posteriorly to the arcus tendineus rectovaginalis. Detachment of this connective tissue from the arcus tendineus fascia pelvis leads to lateral or paravaginal anterior vaginal wall prolapse.

Level III support is composed of the perineal body, superficial and deep perineal muscles, and fibromuscular connective tissue. Collectively, these support the distal one third of the vagina and introitus. The perineal body is essential for distal vaginal support and proper function of the anal canal. Damage to level III support contributes to anterior and posterior vaginal wall prolapse, gaping introitus, and perineal descent.

PATIENT EVALUATION

Symptoms

POP involves multiple anatomic and functional components (Table 24-3). It rarely creates severe morbidity but can greatly diminish quality of life. In contrast, many women with mild to advanced POP lack bothersome symptoms. Thus, initial evaluation must carefully assess prolapse-related symptoms and their quality-of-life effects.

TABLE 24-3. Symptoms Associated with Pelvic Organ Prolapse

Symptoms	Other Possible Causes
Bulge symptoms	
Sensation of vaginal bulging or protrusion	Rectal prolapse
Seeing or feeling a vaginal or perineal bulge	Vulvar or vaginal cyst/mass
Pelvic or vaginal pressure	Pelvic mass
Heaviness in pelvis or vagina	Hernia (inguinal or femoral)
Urinary symptoms	
Urinary incontinence	Urethral sphincter incompetence
Urinary frequency	Detrusor overactivity
Urinary urgency	Hypoactive detrusor function
Weak or prolonged urinary stream	Bladder outlet obstruction (i.e., postsurgical)
Hesitancy	Excessive fluid intake
Feeling of incomplete emptying	Interstitial cystitis
Manual reduction of prolapse to start or complete voiding	Urinary tract infection
Position change to start or complete voiding	
Bowel symptoms	
Incontinence of flatus or liquid/solid stool	Anal sphincter disruption or neuropathy
Feeling of incomplete emptying	Diarrheal disorder
Hard straining to defecate	Rectal prolapse
Urgency to defecate	Irritable bowel syndrome
Digital evacuation to complete defecation	Rectal inertia
Splinting vagina or perineum to start or complete defecation	Pelvic floor dyssynergia
Feeling of blockage or obstruction during defecation	Hemorrhoids
	Anorectal neoplasm
Sexual symptoms	
Dyspareunia	Vaginal atrophy
Decreased lubrication	Levator ani syndrome
Decreased sensation	Vulvodynia
Decreased arousal or orgasm	Other female sexual disorder
Pain	
Pain in vagina, bladder, or rectum	Interstitial cystitis
Pelvic pain	Levator ani syndrome
Low back pain	Vulvodynia
	Lumbar disc disease
	Musculoskeletal pain
	Other causes of chronic pelvic pain

From Barber, 2005a, with permission.

During symptom inventory, two commonly used questionnaires are the Pelvic Floor Distress Inventory (PFDI) and the Pelvic Floor Impact Questionnaire (PFIQ) (Barber, 2005b). The PFDI measures urinary, colorectal, and POP symptoms, whereas the PFIQ assesses POP-related quality of life (Tables 24-4 and 24-5).

Bulge symptoms most strongly correlate with POP, and pelvic pressure or a vaginal or perineal protrusion are typical. These symptoms worsen with prolapse progression (Ellerkmann, 2001). Namely, women with prolapse beyond the hymen are more likely to report a vaginal bulge and have more symptoms than those with prolapse that stops above the hymen (Bradley, 2005; Tan, 2005; Weber, 2001a). If bulge symptoms are the primary complaint, successful replacement of the prolapse with nonsurgical or surgical therapy will usually provide adequate symptom relief.

Urinary symptoms often accompany POP and may include stress urinary incontinence (SUI), urgency urinary incontinence, frequency, urinary retention, recurrent urinary tract infection, or voiding dysfunction. These symptoms may be caused or exacerbated by POP, but correction of prolapse does not guarantee a cure. For example, irritative bladder symptoms (frequency, urgency, and urgency urinary incontinence) do not always improve with prolapse replacement. Moreover, they may be unrelated to the prolapse and require alternative therapy. In contrast, urinary retention, if due to an obstructed urethra, will improve with prolapse treatment (FitzGerald, 2000).

TABLE 24-4. Short Form: Pelvic Floor Impact Questionnaire 7-Item (PFIQ-7)

Please select the best answer to each question below.
Name _____

Has your prolapse affected your:

1. Ability to do household chores (cooking, house cleaning, laundry)?
   _ Not at all _ Mildly _ Moderately _ Severely
2. Physical recreation such as walking, swimming, or other exercises?
   _ Not at all _ Mildly _ Moderately _ Severely
3. Entertainment activities (movies, church)?
   _ Not at all _ Mildly _ Moderately _ Severely
4. Ability to travel by car or bus more than 30 minutes from home?
   _ Not at all _ Mildly _ Moderately _ Severely
5. Participation in social activities outside your home?
   _ Not at all _ Mildly _ Moderately _ Severely
6. Emotional health (nervousness, depression)?
   _ Not at all _ Mildly _ Moderately _ Severely
7. Feeling frustrated?
   _ Not at all _ Mildly _ Moderately _ Severely

TABLE 24-5. Short Form: Pelvic Floor Distress Inventory 22-Item (PFDI-22)[a]

POPDI—6

Do you usually_____, and if so how much are you bothered by:

1. experience pressure in the lower abdomen
2. experience heaviness or dullness in the abdomen or genital area
3. have a bulge or something falling out that you can see or feel in the vaginal area
4. have to push on the vagina or around the rectum to have or complete a bowel movement
5. experience a feeling of incomplete bladder emptying
6. have to push up on a bulge in the vaginal area with your fingers to start or complete urination

CRADI—8

_____, and if so how much are you bothered by it

1. Do you usually feel you need to strain too hard to have a bowel movement
2. Do you usually feel you have not completely emptied your bowels at the end of bowel movement
3. Do you usually lose stool beyond your control if your stool is well formed
4. Do you usually lose stool beyond your control if your stool is loose or liquid
5. Do you usually lose gas from the rectum beyond your control
6. Do you usually have pain when you pass your stool
7. Do you usually experience a strong sense of urgency and have to rush to the bathroom to have a bowel movement
8. Does part of your bowel ever pass through the rectum and bulge outside during or after a bowel movement

UDI—8

Do you usually have _____, and if so, how much are you bothered by:

1. frequent urination
2. leakage related to feeling of urgency
3. leaking related to activity, coughing, or sneezing
4. leakage when you go from sitting to standing
5. small amounts of urine leakage (i.e., drops)
6. difficulty emptying the bladder
7. pain or discomfort in the lower abdomen or genital area
8. pain in the middle of your abdomen as your bladder fills

[a]For each question, patients fill in the blank with each phrase underneath the question. The same multiple choice responses (not at all, mildly, moderately, and severely) used for the PFIQ-7 are used for the PFDI-22.
From Flynn, 2006, with permission.

For these reasons, urodynamic testing is a valuable adjunct in women with urinary symptoms who are undergoing POP treatment (Chap. 23, p. 524). This testing attempts to determine the relationship between urinary symptoms and POP and will help guide therapy. Additionally, consideration may also be given to temporarily placing a pessary to determine if urinary symptoms improve.

Constipation is often present in women with POP, but POP generally is not the cause of constipation. An exception is a posterior vaginal wall defect that bulges as it fills with hard stool. This disrupts the normal mechanics of defecation to create obstruction-type constipation. Thus, constipation symptoms should be thoroughly assessed before proceeding with surgery. In one study of defect-directed posterior repair, constipation resolved postoperatively in only 43 percent of patients (Kenton, 1999). Thus, surgical repair or treatment with a pessary usually will not cure constipation, and it should be evaluated separately (Chaps. 12, p. 268 and 25, p. 569).

Digital decompression by the woman of her posterior vaginal wall, perineal body, or distal rectum to evacuate the rectum is the most common defecatory symptom associated with posterior vaginal wall prolapse (Burrows, 2004; Ellerkmann, 2001). Surgical approaches to this problem provide variable success, and symptom resolution rates range from 36 to 70 percent (Cundiff, 2004; Kenton, 1999).

Anal incontinence of flatus, liquid, or solid stool may also associate with POP. On occasion, prolapse may lead to stool trapping in the distal rectum with subsequent leakage of liquid stool around retained feces. If symptoms are present, a full anorectal evaluation is performed as described in Chapter 25 (p. 561). Most types of anal incontinence would not be expected to improve with surgical repair of prolapse. However, if evaluation reveals an anal sphincter defect as the cause of anal incontinence, anal sphincteroplasty may be performed concurrently with prolapse repair.

Female sexual dysfunction is frequently multifactorial and includes psychosocial factors, urogenital atrophy, aging, and male sexual dysfunction (Chap 14, p. 312). Often, sexual dysfunction also is seen in women with POP. However, study findings are inconsistent. In one study, a validated sexual function questionnaire was used to compare intercourse frequency, libido, dyspareunia, orgasmic function, and vaginal dryness in women with and without POP (Weber, 1995). No differences were seen between the two groups. In another, pelvic floor symptoms were associated with dyspareunia, reduced arousal, and infrequent orgasm (Handa, 2008). In addition, sexual dysfunction was worse in women with symptomatic prolapse versus those with asymptomatic prolapse. In one evaluation, decreased sexual activity was associated with shorter vaginal length, and one quarter of women avoided sexual activity due to pelvic floor symptoms (Edenfield, 2015). Accordingly, women with an obstructing bulge as a cause of sexual dysfunction may benefit from therapy to reduce the prolapse. Unfortunately, some prolapse procedures such as posterior repair with levator plication and vaginal placement of mesh may contribute to postoperative dyspareunia. Thus, sexual dysfunction should be factored during treatment planning (Ulrich, 2015).

Pelvic pain and back pain are common complaints in women with POP, but little evidence supports a direct association (Heit, 2002; Swift, 2003). Some suggest that low back pain in a patient with POP may be caused by altered body mechanics. However, if pain is a primary symptom, other sources should be sought (Chap. 12, p. 257). Without an identifiable etiology, temporary pessary placement may determine if prolapse reduction will improve pain symptoms. Referral to a physical therapist may also shed light on a connection among prolapse, altered body mechanics, and pain.

Importantly, although POP is associated with varied complaints, symptoms and their severity do not always correlate well with advanced-stage POP. In addition, apical, anterior, or posterior wall prolapse each can cause similar symptoms (Jelovsek, 2005; Kahn, 2005; Weber, 1998). Thus, when planning surgical or nonsurgical therapy, realistic expectations should be set with regard to symptom relief. A patient is informed that symptoms directly related to prolapse such as vaginal bulge and pelvic pressure are likely to lessen with a successful anatomic repair. However, constipation, back pain, and urinary urgency and frequency may or may not improve.

Physical Examination

Perineal Examination

Physical examination begins with a full body systems evaluation to identify pathology outside the pelvis. Cardiovascular, pulmonary, renal, or endocrinologic disease may affect treatment choices and are ideally identified early.

The initial pelvic examination is performed with a woman in lithotomy position. The vulva and perineum are examined for signs of vulvar or vaginal atrophy or other abnormalities. A neurologic examination of sacral reflexes is performed using a cotton swab. First, the *bulbospongiosus reflex* is elicited by tapping or sweeping lateral to the clitoris and observing contraction of the bulbospongiosus muscles bilaterally. Second, evaluation of anal sphincter innervation is completed by sweeping lateral to the anus and observing a reflexive contraction of the anus, known as the *anal wink reflex*. Intact reflexes suggest normal sacral pathways. Still, they may be absent in women with intact neurologic functioning.

POP examination begins by asking a woman to attempt a Valsalva maneuver before placing a speculum in the vagina (Fig. 24-8). Patients who are unable to adequately complete a Valsalva maneuver are asked to cough. This "hands-off" approach more accurately displays true anatomy. For example, with speculum examination, structures are artificially lifted, supported, or displaced. During assessment, the specific prolapsing vaginal compartment, its degree of descent, and changes in genital hiatus diameter are determined.

A woman is asked to describe the extent of prolapse beyond the hymen during real-life activities. This degree may be conveyed in terms of inches. Alternatively, a mirror may be placed at the perineum. Here, the patient can visually confirm that the examiner is seeing the true extent of the prolapse.

POP is a dynamic condition that responds to the effects of gravity and intraabdominal pressure. It frequently worsens over the course of a day or during physical activity. Thus, POP

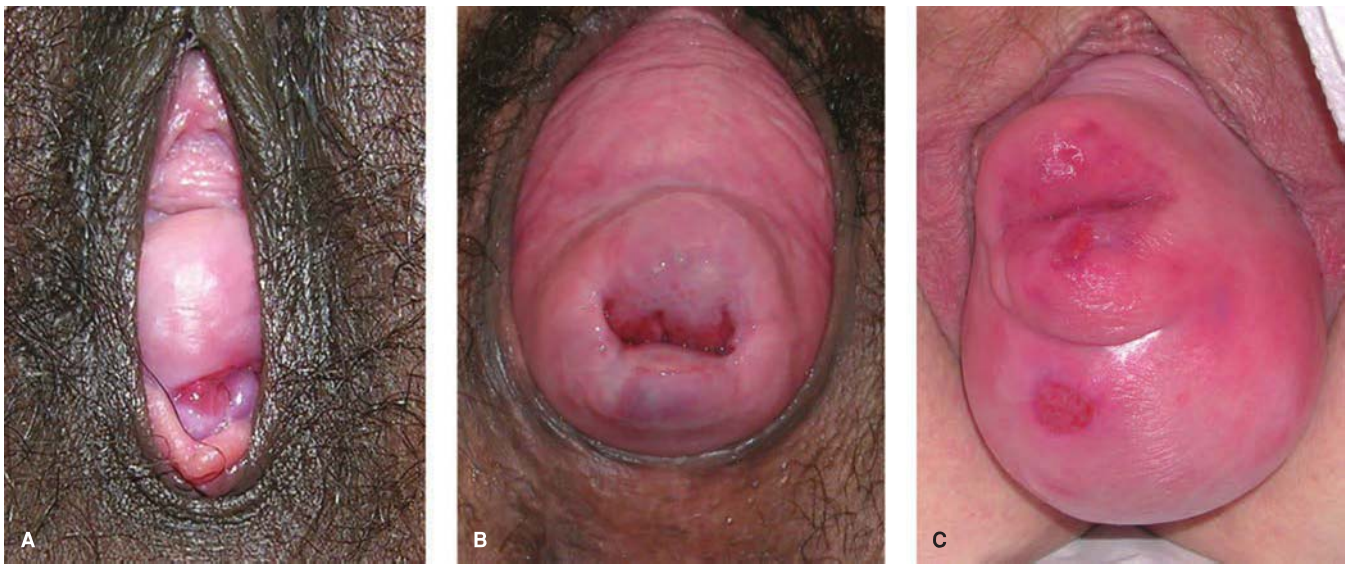

FIGURE 24-8 A. Stage 2. This stage is defined by the most distal edge of the prolapse lying within 1 cm of the hymeneal ring. **B.** Stage 3. This stage is defined by the most distal portion of the prolapse being >1 cm below the plane of the hymen, but protruding no farther than 2 cm less than the total vaginal length in centimeters. **C.** Stage 4. This stage is defined as complete or near complete eversion.

might not be evident during office examination early in the morning. If the full extent of prolapse cannot be demonstrated, a woman should be examined in a standing position and during Valsalva maneuver.

Vaginal Examination

All POP-Q points, except TVL, are measured during patient Valsalva. The genital hiatus and perineal body are measured first (Fig. 24-9). TVL is next measured by placing a marked ring forceps or a ruler at the vaginal apex and noting the distance to the hymen. This is replaced by a bivalve (Graves) speculum, which is inserted to the vaginal apex. It displaces the anterior and posterior vaginal walls, and points C and D are measured during a Valsalva maneuver. During the maneuver, the speculum is slowly withdrawn to assess descent of the apex.

A split speculum is then used to displace the posterior vaginal wall and allow viewing of the anterior wall and measurement of points Aa and Ba. Attempts are made to characterize the anterior vaginal wall defect. Sagging lateral vaginal sulci with vaginal rugae present suggest a *paravaginal defect*, that is, a lateral loss of support (Fig. 24-10). A central bulge and loss of vaginal rugae is called a *midline* or *central defect* (see Fig. 24-6). If loss of support appears to arise from detachment of the anterior vaginal wall's apical segment, it is termed a *transverse* or *anterior apical defect* (Fig. 24-11). Transverse defects are assessed by replacing the apex with a split-speculum blade and observing whether the prolapse descends during Valsalva maneuver.

The split speculum is then rotated 180 degrees to displace the anterior wall and allow examination of the posterior wall. Points

FIGURE 24-9 A. Measurement of the genital hiatus (Gh). For POP-Q evaluation, a sponge stick is marked at 1-, 2-, 3-, 4-, 5-, 7.5-, and 10-cm increments. Measurement is obtained with a woman performing maximum Valsalva maneuver. **B.** Measurement of the perineal body. **C.** Measurement of points Aa and Ba. Aa is a discrete point lying 3 cm proximal to the urethral meatus and is measured in relation to the hymen. During measurement, a split speculum displaces the posterior vaginal wall, but downward traction is avoided, as this causes artificial descent of the anterior vaginal wall.

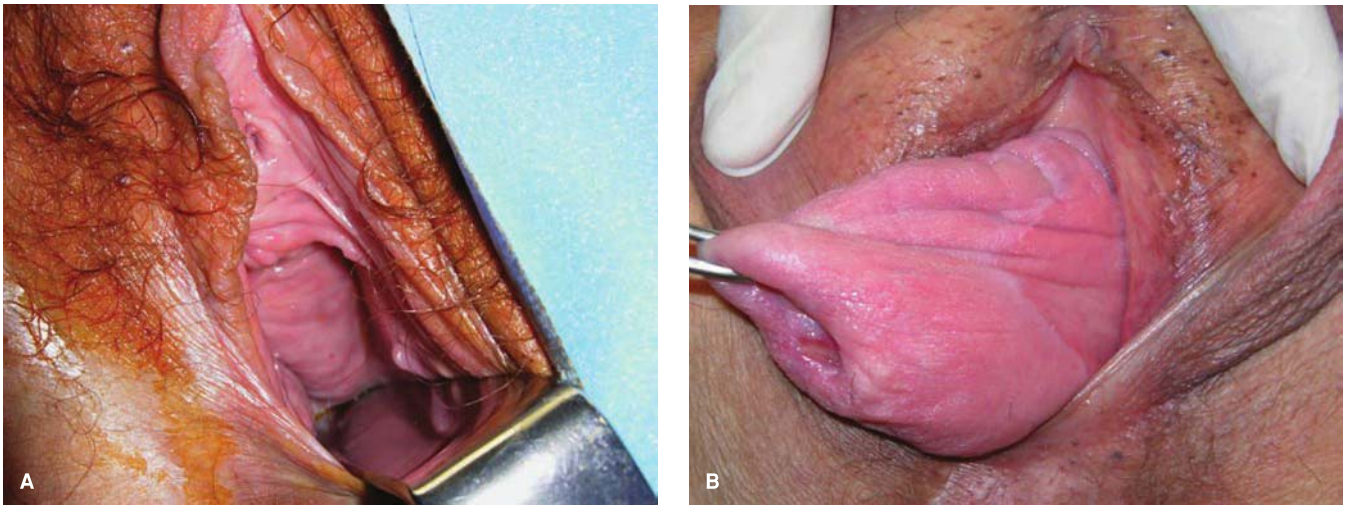

FIGURE 24-10 A. Normal lateral support as noted by normal positioning of the vaginal sulci. **B.** Complete loss of lateral support, shown as absent lateral sulci.

Ap and Bp are measured (Fig. 24-12). If the posterior vaginal wall descends, attempts are made to determine if a posterior vaginal wall defect or an enterocele is present. An enterocele can be definitively diagnosed by observing small-bowel peristalsis behind the vaginal wall (Fig. 24-13). In general, bulges at the apical segment of the posterior vaginal wall implicate enteroceles. As a further diagnostic step, a clinician's index finger is placed in the rectum and thumb on the posterior vaginal wall. Small bowel may be palpated between the rectum and vagina, confirming enterocele.

Differentiation of midline, lateral, apical, and distal defects of the anterior and posterior vaginal walls has poor inter- or intraexaminer reliability. However, individual evaluation may help assess prolapse severity and clarify anatomy if surgical correction is planned (Barber, 1999; Whiteside, 2004).

As mentioned, apical prolapse is thought to cause most anterior and posterior wall descent. Thus, the apex is replaced to its normal position during evaluation. If this maneuver restores anterior and posterior support, it can be determined

FIGURE 24-12 Split speculum displaces the anterior vaginal wall. This allows for measurement of points Ap and Bp. Ap is always defined as a discrete point lying 3 cm proximal to the hymen.

FIGURE 24-11 Transverse vaginal wall defect. Note detachment of the anterior vaginal wall from the apex and the presence of rugae, which suggests that this is not a midline or central defect.

FIGURE 24-13 During evaluation, small-bowel peristalsis may be noted behind the vaginal wall. Such enteroceles are most commonly noted at the vaginal apex, although anterior and posterior vaginal wall enteroceles may occur.

FIGURE 24-14 Pelvic floor muscle assessment. The index finger is placed 2 to 3 cm inside the hymen at 4 and 8 o'clock. Both resting and contraction tone and strength are evaluated.

that restoration of apical support will improve prolapse in all three compartments.

Bimanual examination is performed to identify other pelvic pathology. We strongly recommend assessment of pelvic floor musculature (Fig. 12-4, p. 260). This examination is essential if pelvic floor rehabilitation is considered for treatment. During part of the evaluation, an index finger is placed 1 to 3 cm inside the hymen, at 4 and then 8 o'clock (Fig. 24-14). Muscle resting tone and strength is assessed using the 0 through 5 Oxford grading scale, in which 5 represents normal tone and strength (Laycock, 2002). Muscle symmetry also is evaluated. Asymmetric muscles, with palpable defects or scarring, may be associated with a prior obstetric forceps delivery, episiotomy, or laceration.

APPROACH TO TREATMENT

For women who are asymptomatic or mildly symptomatic, expectant management is appropriate. The natural history of prolapse is unknown, and many women will never develop symptoms. Thus, invasive therapy is typically not selected for asymptomatic women, as risks likely outweigh benefits.

For women with significant POP or for those with bothersome symptoms, nonsurgical or surgical therapy is an option. Treatment choice is influenced by symptom type and severity, age, medical comorbidities, factors for recurrence, and desire for future sexual function and/or fertility. Once these are assessed, options and their success rates are discussed. In the simplest case, a patient with prolapse of the vaginal apex beyond the hymen, whose only symptom is bulge or pelvic pressure, could be offered pessary or surgical repair. In a more complex case, a woman with prolapse beyond the hymen may note a bulge, constipation, urgency urinary incontinence, and pelvic pain. Symptoms would be ranked by severity and importance of resolution. To address all complaints, therapy might involve a pessary or surgery for bulge symptoms, and nonsurgical treatment of constipation, incontinence, and pelvic pain.

NONSURGICAL TREATMENT

Pessary

Pessary Indications

Various vaginal devices can be inserted to support vaginal prolapse. Today's pessaries are appropriate effective options for prolapse of anterior, posterior, or apical compartments. Usually made of silicone or inert plastic, pessaries are typically safe and simple to manage. In one randomized trial, women with stage 1 through 3 POP were treated with either pelvic floor muscle training (PFMT) alone or a combination PFMT plus a vaginal pessary. At 12 months, women in both groups had improved scores on the POP distress inventory and the POP impact questionnaire. However, the mean score differences were higher in the pessary group (Cheung, 2016).

Pessaries may also help some women with prolapse and associated urinary incontinence. One randomized trial compared two pessary types for relief of prolapse symptoms and urinary complaints. Pessaries modestly improved urinary obstructive, irritative, and stress symptoms (Schaffer, 2006).

Pessaries can also aid diagnosis and treatment prognosis. First, symptoms may not correlate with prolapse type or severity. Short-term pessary use may help clarify this relationship. Even if a patient declines long-term pessary use, she may agree to a short trial to determine if her chief complaint is improved or resolved. Second, a pessary may also be placed prior to surgery to identify which women are at risk for urinary incontinence after a prolapse-correcting procedure (Chaikin, 2000; Liang, 2004).

Pessary Selection

Pessaries are divided into support and space-filling categories (Fig. 24-15). Support pessaries, such as the ring pessary, use a spring mechanism that rests in the posterior fornix and against the symphysis pubis. Vaginal support derives from elevation of the vaginal apex by the spring, which is supported by the symphysis pubis. Ring pessaries may be constructed as a simple circular ring or as a ring with support that looks like a large contraceptive diaphragm (Fig. 24-16). The diaphragm portion of a support ring can serve as a shelf to limit anterior vaginal wall descent. When properly fitted, the device should lie behind the pubic symphysis anteriorly and behind the cervix posteriorly.

In contrast, space-filling pessaries maintain their position by creating suction between the pessary and vaginal walls (cube), by creating a diameter larger than the genital hiatus (donut), or by both mechanisms (Gellhorn). The Gellhorn is often used for moderate to severe prolapse and for complete procidentia. It contains a concave disc that fits against the cervix or vaginal cuff and has a stem that is positioned just cephalad to the introitus. The concave disc supports the vaginal apex by creating suction, and the stem is useful for device removal. Of all pessaries, the two most commonly used and studied devices are the ring and the Gellhorn pessaries.

Patient Evaluation and Pessary Placement

A patient must be an active participant in the treatment decision to use a pessary. Its success depends on her ability to care for the

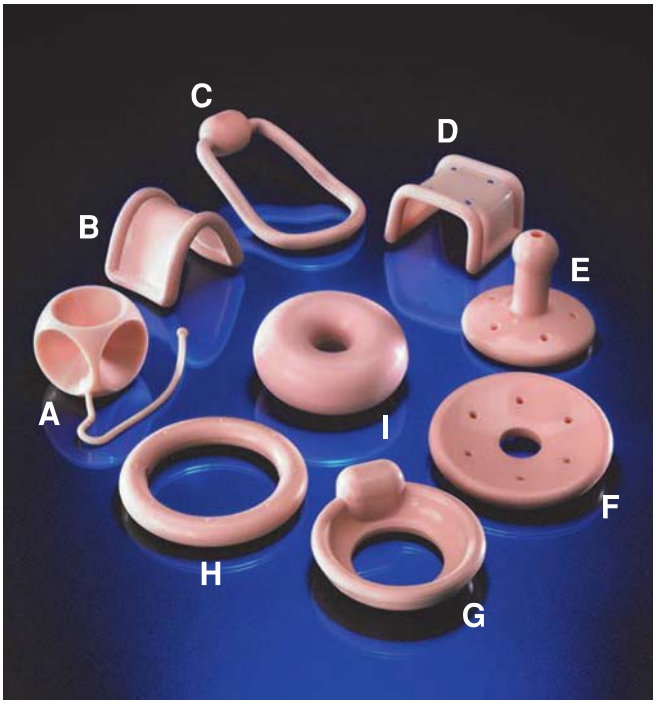

FIGURE 24-15 Types of Milex pessaries. **A.** Cube pessary. **B.** Gehrung pessary. **C.** Hodge with knob pessary. **D.** Regula pessary. **E.** Gellhorn pessary. **F.** Shaatz pessary. **G.** Incontinence dish pessary. **H.** Ring pessary. **I.** Donut pessary. device—either alone or with the assistance of a caregiver—and her willingness and availability to come for subsequent evaluations. Vaginal atrophy is ideally treated before or concomitantly with pessary initiation, and options are found in Table 22-11 (p. 498). In women who are suitable candidates for estrogen therapy, vaginal estrogen cream is recommended. In one regimen, 1 g of conjugated equine estrogen cream (Premarin cream) is inserted nightly for 2 weeks, then two times per week thereafter. Vaginal ospemifene is another option.

Device selection integrates patient factors such as hormonal status, sexual activity, prior hysterectomy, and stage and site of POP. After a pessary is chosen, a woman is fitted with the largest size that can be comfortably worn. If a pessary is ideally fitted, a patient is not aware of it. As a woman ages and gains or loses weight, alternate sizes may be required.

FIGURE 24-16 Milex ring pessary with support. (Reproduced with permission of CooperSurgical, Inc., Trumbull, CT.)

Generally, a patient is fitted with a pessary while in the lithotomy position after she has emptied her bladder. A digital examination is performed to assess vaginal length and width, and an initial estimation of pessary size is made. For ring pessary placement, the device is held in the clinician's dominant hand in a folded position. Lubricant is placed on the vaginal introitus or on the pessary's leading edge. While holding the labia apart, a provider inserts the pessary by pushing it cephalad and against the posterior vaginal wall. Once the upper vagina is reached, the pessary is released and it opens. Next, an index finger is directed into the posterior vaginal fornix to ensure that the cervix is resting above the pessary. In a well-sized device, the clinician's finger should barely slide between the lateral edges of the ring pessary and the vaginal sidewall. The pessary ideally fits snugly but not tightly against the symphysis pubis and the posterior and lateral vaginal walls. Excessive pressure increases the risk for pain. Figure 24-17 shows Gellhorn pessary placement.

Following pessary placement, a woman is prompted to bear down, which might dislodge an improperly fitted pessary. She should be able to stand, walk, cough, and urinate without difficulty or discomfort. Instruction on removal and placement then follows. For removal of a ring pessary, an index finger is inserted into the vagina to hook the ring's edge. Traction is applied along the vaginal axis to bring the ring toward the introitus. Here, it may be grasped by the thumb and index finger and removed.

Ideally, a pessary is removed nightly to weekly, washed in soap and water, and replaced the next morning. Women also receive instructions describing the management of commonly encountered problems (Table 24-6). After initial placement, a return visit may follow in 1 to 2 weeks. For patients comfortable with their pessary management, return visits may be semiannual. If the patient and the provider are motivated, most women can be taught to self-manage a pessary. For those unable or unwilling to remove and replace a device themselves, a pessary may be removed and the patient's vagina inspected at the provider's office every 2 or 3 months. Delaying visits longer than this may lead to problematic discharge and odor.

Pessary Complications

Serious complications such as erosion into adjacent organs are rare with proper use and usually result only after years of neglect. At each return visit, the pessary is removed, and the vagina is inspected for erosions, abrasions, ulcerations, or granulation tissue (Fig. 24-18). Vaginal bleeding is usually an early sign and should not be ignored. *Pessary ulcers* or abrasions are treated by changing the pessary type or size to alleviate pressure points or by removing the pessary completely until sites heal. Treatment of vaginal atrophy with local estrogen is commonly required. Alternatively, water-based lubricants applied to the pessary may help prevent these complications. *Prolapse ulcers* have the same appearance as pessary ulcers, however, the former result from the prolapsed bulge rubbing against patient clothing. These are treated by replacing the prolapse either with a pessary or by surgery. Topical hormone therapy can be an interim adjunct.

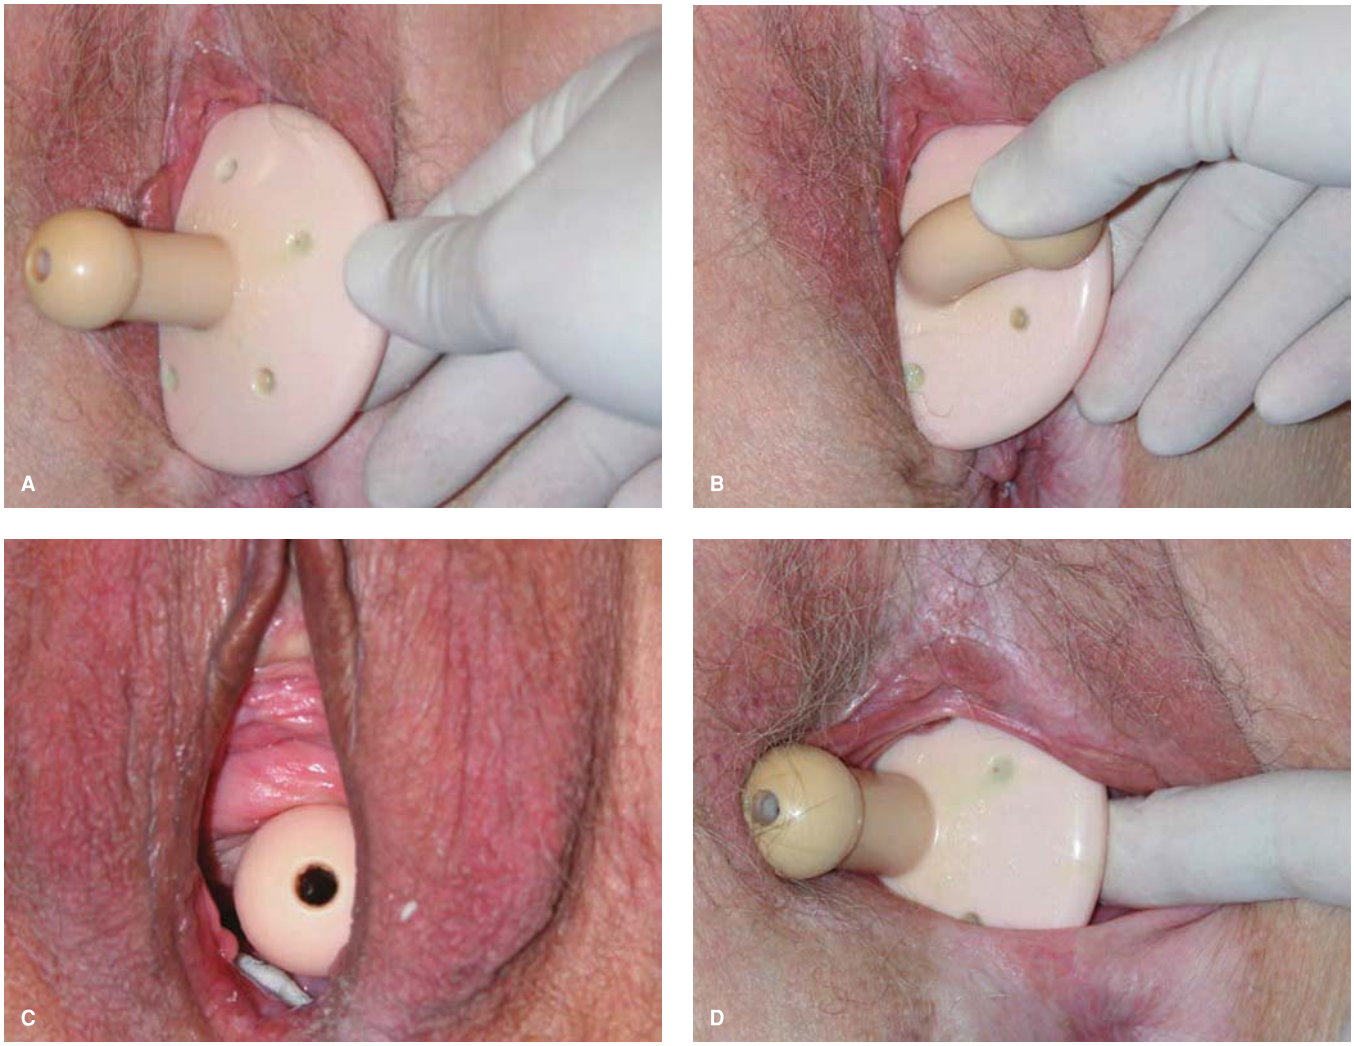

FIGURE 24-17 Technique for placement and removal of a Gellhorn pessary. Figures **A**–**C** show placement. **D.** To remove a Gellhorn pessary, an index finger is placed behind the disk and suction is broken prior to removal.

FIGURE 24-18 Granulation tissue involving the anterior and posterior vaginal wall resulting from pessary trauma.

Of other related symptoms, pelvic pain is not considered normal and usually indicates a device that is too large. Second, all pessaries tend to trap vaginal secretions and obstruct normal drainage to some degree. The resulting odor may be managed by encouraging nighttime device removal, washing, and reinsertion the next day on a more frequent basis. Alternatively, a woman may use a pH-based deodorant gel (Trimo-San gel) once or twice weekly or may douche with warm water. Trimo-San gel helps restore and maintain normal vaginal acidity that aids in reducing odor-causing bacteria.

Pelvic Floor Muscle Training

Also known as *Kegel exercises*, the steps of pelvic floor muscle training are described fully in Chapter 23 (p. 527). To some degree, these exercises may limit POP progression and alleviate symptoms, and two hypotheses describe their benefits (Bø, 2004). First, with PFMT, women learn to consciously contract muscles before and during increases in abdominal pressure. This prevents organ descent. Second, regular muscle strength training builds permanent muscle volume and structural support.

TABLE 24-6. Guidelines for Pessary Care

Pessary type_____
Size_____

1. After your initial pessary fitting is successful, you will be asked to return for a follow-up appointment in about 2 weeks. The purpose of this visit is to check the pessary and examine the vagina to ensure that it is healthy. Follow-up appointments will follow this schedule:
   1st year: every 3–6 months
   2nd year and beyond: every 6 months
   You may learn to care for the pessary yourself. For those patients who can remove and insert the pessary themselves, we recommend weekly overnight removal and cleansing of the pessary with soap and warm water. These patients should see the doctor at least once per year.
2. The following is a list of problems you may encounter with the pessary and our recommendations for their management.

Problem	Management
A. The pessary falls out.	Keep the pessary and notify your doctor's office. An appointment will be made. It may be possible that a change in the size or the type of pessary is needed.
B. You experience pelvic pain.	Notify your doctor's office. If the pessary has slipped and you can remove it, do so. Otherwise, have your doctor remove the pessary. A change in pessary size or type may be needed.
C. Vaginal discharge and odor.	You can douche with warm water and you may want to try using Trimo-San vaginal gel 1–3 times a week.
D. Vaginal bleeding.	Vaginal bleeding may be a sign that the pessary is irritating the lining of the vagina. Call your doctor's office and arrange an appointment.
E. Leaking from the bladder.	Sometimes, the support provided by the pessary will cause leaking from the bladder. Notify your doctor and discuss this problem.

Trimo-San (Oxyquinoline, Milex Products, Chicago, IL) helps restore and maintain the normal vaginal acidity that helps reduce odor-causing bacteria.
From Farrell, 1997, with permission.

In one randomized trial, women with stages 1 through 3 of POP were assigned a regimen or were given a prolapse lifestyle advice leaflet (Hagen, 2017). After 2 years, prolapse symptom severity scores and bladder and bowel symptoms in the PFMT group were lower. Although differences were small, women in the PFMT group also were more likely to perceive a health-related benefit. Similarly, in a metaanalysis of 13 trials, women receiving PFMT compared with those not undergoing therapy showed greater improvement in prolapse symptoms, POP-Q stage, and bowel and bladder symptoms (Li, 2016).

PFMT has minimal risk and expense. For this reason, it may be offered to asymptomatic or mildly symptomatic women who are interested in treating symptoms and/or preventing POP progression or who decline other treatments.

SURGICAL TREATMENT

In preparing for prolapse-correcting surgery, each patient should understand anticipated results, and a surgeon should factor a patient's goals and expectations. Symptoms and quality-of-life issues, such as those in Tables 24-4 and 24-5, are ranked by the patient, and elected treatment is directed towards those highest on her list (Mamik, 2013).

All endpoints may not be obtainable, and a surgeon should provide the patient with best estimates of goal attainment based on scientific evidence and the surgeon's personal experience. Importantly, in published studies, treatment success rates vary widely based on the definition of success. Generally, patients seek long-term relief of symptoms, whereas surgeons may view surgical success as restoration of normal anatomy. Thus, the surgeon and the patient must agree on desired endpoints.

Reconstructive Procedures

POP surgeries are viewed as either reconstructive ones, which attempt to restore normal pelvic anatomy, or obliterative types, which permanently occlude the vagina (p. 554). Of these, reconstructive procedures are more commonly performed for POP, and multiple options are available. Some are completed from a vaginal approach, whereas others use laparotomy, laparoscopy, or robotic surgery.

With a vaginal approach, patients typically resume ambulation, diet, and routine activities early, as abdominal wall entry and bowel manipulation are avoided. Operative times are usually shorter. These qualities may be especially attractive for elderly women or those with significant comorbidities.

Abdominal options offer durable outcomes, which may offer advantages to a woman with POP recurrence after prior vaginal surgery or one believed to be at higher recurrence risk. The latter is typified by a young woman with severe prolapse

or a woman with chronically increased intraabdominal pressure (Benson, 1996; Maher, 2004). Another consideration is sexual activity. Some evidence suggests lower dyspareunia rates and less vaginal shortening after sacrocolpopexy, which is one abdominal approach option.

Laparoscopic and robotic approaches to prolapse repair are becoming more common. They offer smaller incisions and shorter hospital stay than laparotomy. One randomized trial compared open and laparoscopic sacrocolpopexy and found similar anatomic and subjective outcomes after 1 year (Freeman, 2013). Perceived advantages to the laparoscopic approach such as earlier return to usual activities, however, were not seen. Several small randomized trials also have compared laparoscopic and robotic sacrocolpopexy (Anger, 2014; Paraiso, 2011). In general, these studies showed similar short-term outcomes but greater expense with robot use.

Thus, a provider should recommend an operation specific to the patient's anatomy, treatment goals, and health characteristics. *One size does not fit all.*

Surgical Plan

Reconstructive prolapse repair will often combine procedures that each address different vaginal compartments. However, the decision regarding which compartment(s) to repair is not always straightforward. In the past, a defect-directed approach to prolapse repair was preferred. With this strategy, all current or potential defects are evaluated and repaired. However, current expert opinion suggests that latent defects do not always warrant repair. Additionally, repair of one asymptomatic compartment can redirect pressure vectors and create de novo POP and symptoms. For instance, repair of an asymptomatic posterior vaginal wall prolapse may lead to dyspareunia. Or, apical prolapse correction can raise later anterior vaginal wall prolapse rates. Thus, surgery in general is planned to relieve *current* symptoms.

Vaginal Apex

Vaginal apex resuspension is a vital component of POP repair and an important focus in surgery planning (Brubaker, 2005). The vaginal apex can be resuspended with several procedures that include sacrocolpopexy, sacrospinous ligament fixation, or uterosacral ligament vaginal vault suspension. These are all illustrated in Chapter 45 (p. 1124). In one worldwide analysis of nearly 700,000 POP procedures, 70 percent of apical repairs were performed vaginally, whereas 17 percent were sacrocolpopexy procedures (Haya, 2015). Compared with vaginal options, sacrocolpopexy offers lower postoperative rates of POP recurrence, SUI, and dyspareunia but carries longer operative and recovery times (Maher, 2011, 2016). Similarly, in three large randomized trials that compared open sacrocolpopexy and vaginal repair options, sacrocolpopexy yielded a sixfold higher rate of POP resolution (Rogers, 2018). Success was defined as no bulge symptoms, no prolapse beyond the hymen, and no retreatment 2 years after surgery. Despite these data, consensus regarding the most effective approach is still lacking.

Of these, *sacrocolpopexy* suspends the vaginal vault to the sacrum using synthetic mesh. Advantages include the procedure's durability over time and conservation of normal vaginal anatomy. For example, compared with other vault suspension procedures, sacrocolpopexy offers greater vaginal apex mobility and minimizes vaginal shortening. In addition, sacrocolpopexy provides enduring correction of apical prolapse, and long-term success rates approximate 90 percent. This procedure may be used primarily or as a second surgery for women with recurrences after failure of other prolapse repairs.

Sacrocolpopexy may be performed as an abdominal, laparoscopic, or robotic procedure. When hysterectomy is performed in conjunction with sacrocolpopexy, consideration is given to performing a supracervical rather than a total abdominal hysterectomy. With the cervix left in situ, the mesh is attached to the cervical stump. The mesh is not exposed to vaginal flora, which occurs when the vagina is opened with total hysterectomy (Griffis, 2006). The risk of postoperative mesh erosion at the vaginal apex is thus diminished (McDermott, 2009). In addition, the strong connective tissue of the cervix allows for an additional anchoring point for the mesh. Other important consenting points with total or supracervical hysterectomy are found in Chapter 43 (p. 957).

Sacrospinous ligament fixation (SSLF) is one of the most popular apical suspension options. With it, the vaginal apex is suspended to the sacrospinous ligament unilaterally or bilaterally using a vaginal approach that does not enter the peritoneum (extraperitoneal). After SSLF, recurrent apical prolapse is uncommon. However, anterior vaginal wall prolapse develops postoperatively in 6 to 28 percent of patients. This is thought to develop from surgical deflection of the vagina posteriorly, which redirects abdominal forces toward the anterior vaginal wall (Barber, 2014; Benson, 1996; Morley, 1988; Paraiso, 1996). SSLF complications include neurologic and buttock pain from nerve involvement with surgical ligatures in up to 12 percent of patients and vascular injury in 1 percent (Barber, 2014; Sze, 1997a,b). Although infrequent, significant and life-threatening hemorrhage can follow injury to blood vessels located behind the sacrospinous ligament.

Uterosacral ligament vaginal vault suspension is another apical surgery. With this, the vaginal apex is attached to remnants of the uterosacral ligament at the level of the ischial spines or higher. Performed vaginally or abdominally, the uterosacral ligament suspension (USLS) is believed to replace the vaginal apex to a more anatomically correct position than SSLF (Barber, 2000; Maher, 2004; Shull, 2000). Because of this angle difference, USLS compared with SSLF was thought to reduce the rates of anterior vaginal wall prolapse (Shull, 2000). However, the randomized OPTIMAL trial, which compared the two operations, did not show a difference in anterior vaginal wall prolapse recurrence rates. Moreover, investigators found no significant differences in anatomic or functional outcomes between the two procedures at 2 years (Barber, 2014).

Hysterectomy or Uterine-Preserving Surgeries

In the United States, hysterectomy is often completed concurrently with POP surgery, whereas in many European countries, it is rarely performed during pelvic floor reconstruction. If the apex is not prolapsed, hysterectomy need not be incorporated into POP repair. However, with apical prolapse, hysterectomy readily allows the vaginal apex to be resuspended with the just-described apical suspension procedures. Otherwise, procedures must be

modified or specific uterine suspension procedures selected to accommodate the retained uterus.

The rationale for hysterectomy is that resuspension of the vaginal apex can more successfully be accomplished after the uterus is removed. However, one recent systematic review concluded that uterine-preserving prolapse surgeries offer shorter operating times, less blood loss, and lower risk of mesh exposure, yet provide similar short-term prolapse outcomes compared with POP repairs coupled with hysterectomy (Meriwether, 2018). Other perceived advantages of uterus retention include faster recovery as well as maintenance of fertility, sexual function, a sense of femininity, and quality of life (Bradley, 2018). In preference studies, a uterine-preserving prolapse repair was preferred by 36 to 60 percent of patients if anticipated efficacy was equivalent whether the uterus was retained or removed (Frick, 2013; Korbly, 2013). Indeed, uterine-preserving apical prolapse procedures are gaining popularity in the United States. These made up 1.8 percent of inpatient POP procedures in 2002 and 5 percent in 2012 (Madsen, 2017). Notably, uterine or cervical conditions that may raise the risk for later hysterectomy but that are unrelated to prolapse should be factored.

Hysteropexy Types

An apical prolapse repair that preserves the uterus is called a *hysteropexy*. Variations may be completed by vaginal, abdominal, laparoscopic, and robotic approaches and may be augmented with mesh.

With *sacrospinous hysteropexy*, a vaginal approach and extraperitoneal access allows sutures to be driven through the supporting sacrospinous ligament. To recreate apical support, these sutures are then attached to the cervix or uterosacral ligament. Similar to SSLF, the vaginal axis is shifted posteriorly and thereby adds potential risk for anterior vaginal wall prolapse.

With *vaginal uterosacral hysteropexy*, vaginal culdotomy and intraperitoneal entry provide access to the uterosacral ligaments. Two sutures are placed in each ligament and then attached to the uterine cervicoisthmic junction for support (Romanzi, 2012).

With *vaginal mesh hysteropexy*, a T-shaped mesh is anchored to the sacrospinous ligaments bilaterally and attached to the cervix and anterior vaginal wall (Gutman, 2017). Previously marketed mesh kits are no longer available.

With *sacrohysteropexy*, two pieces of synthetic mesh are attached to the proximal vagina and cervix on their anterior and posterior surfaces. The mesh is then secured to the anterior longitudinal ligament at the sacrum similar to sacrocolpopexy (Gutman, 2017).

With *abdominal uterosacral hysteropexy*, sutures are placed through the uterosacral ligament and then through the cervix (Haj Yahya, 2018). For this surgery, robotic or laparoscopic approaches are described.

Pregnancy outcomes after hysteropexy are not well studied. In general, most experts believe that women with symptomatic prolapse who have not completed childbearing may be offered conservative management with a pessary as first-line therapy.

Anterior Compartment

Many procedures for anterior vaginal wall prolapse repair have been described. Historically, anterior colporrhaphy was the most common, yet long-term anatomic success rates are poor. In one randomized trial of three anterior colporrhaphy techniques, Weber and associates (2001b) found a low rate of anatomic success. Specifically, satisfactory anatomic results were obtained in only 30 percent of their traditional midline plication group, 46 percent of the ultralateral repair group, and 42 percent of the group undergoing traditional plication plus lateral reinforcement with polyglactin 910 synthetic mesh. These differences were not statistically significant. However, despite anatomic results that may appear suboptimal, symptom relief from anterior colporrhaphy can be acceptable. For example, a re-analysis of data from this trial used clinically relevant definitions of success that included no prolapse beyond the hymen, no prolapse symptoms, and no retreatment requests. With these, 88 percent of subjects met the definition of success (Chmielewski, 2011).

Anterior vaginal wall prolapse may result from central (midline), lateral, or apical fibromuscular defects. If a central defect is suspected, anterior colporrhaphy is a reasonable option (Chap. 45, p. 1114). For an anterior apical defect, in which the fibromuscular layer is detached from the vaginal apex, an apical suspension procedure described in the prior sections will resuspend the anterior vaginal wall to the apex and improve anterior wall prolapse.

Last, if a lateral defect is suspected, paravaginal repair can be performed through a vaginal, abdominal, laparoscopic, or robotic route (Chap. 45, p. 1117). Paravaginal repair is performed by reattaching the fibromuscular layer of the vaginal wall to the arcus tendineus fascia pelvis.

Mesh or biomaterial has also been used in conjunction with anterior colporrhaphy. Either is used to reinforce the vaginal wall and is frequently sutured in place laterally. Several studies show a better anatomic outcome with these compared with repair of existing tissue (native tissue repair) (Maher, 2016). However, functional or quality-of-life outcomes do not differ. Complications with mesh include vaginal erosions in 10 percent of cases, pain, and dyspareunia (Sung, 2008). For these reasons, the use of mesh for anterior vaginal wall prolapse remains controversial and is discussed further on page 553 (American College of Obstetricians and Gynecologists, 2017). Although free mesh is still available, mesh kits have been removed from the market in the United States and other countries.

Posterior Compartment

Posterior vaginal wall prolapse may be due to enterocele or a distal vaginal wall defect. Enterocele is defined as herniation of small bowel through a discontinuity in posterior vaginal wall fibromuscular layers, usually at the vaginal apex. Accordingly, enterocele repairs strive to reattach these fibromuscular layers.

Posterior vaginal wall defects without such herniation are repaired with one of several techniques, which are illustrated in Chapter 45 (p. 1119). Of these, traditional posterior colporrhaphy aims to rebuild the attenuated fibromuscular layer between the rectum and vagina by performing a midline fibromuscular plication. The anatomic cure rate is 76 to 96 percent, and most studies report a greater than 75-percent improvement rate of bulge symptoms (Cundiff, 2004). To narrow the genital hiatus and prevent recurrence, some surgeons plicate the levator ani

muscle concurrently with posterior repair. However, this practice may contribute to dyspareunia rates of 12 to 27 percent (Kahn, 1997; Mellegren, 1995; Weber, 2000). Thus, it may be best avoided in women who are sexually active.

Site-specific posterior repair is an approach based on the assumption that specific tears in the fibromuscular layer can be repaired in a discrete fashion. Defects may be midline, lateral, distal, or superior. This approach is conceptually analogous to a fascial hernia, in which the fascial tear is identified and repaired. Thus, its theoretical advantage lies in its restoration of normal anatomy rather than plication of tissue in the midline. Anatomic cure rates range from 56 to 100 percent, similar to that with traditional posterior colporrhaphy (Muir, 2007). However, anatomic and functional long-term outcomes have yet to be reported.

Mesh reinforcement with allograft, xenograft, or synthetic mesh has been used in conjunction with posterior colporrhaphy and site-specific repair to help reduce prolapse recurrence. However, the efficacy and safety of graft augmentation in the posterior vaginal wall has not been established. Paraiso and coworkers (2006) randomly assigned 105 women to posterior colporrhaphy, site-specific repair, or site-specific repair plus a graft using porcine small intestine. After 1 year, those with graft augmentation had a significantly higher anatomic failure rate (46 percent) than those who received site-specific repair alone (22 percent) or posterior colporrhaphy (14 percent). More research is needed to determine the safety, efficacy, and optimal material for posterior wall graft augmentation. Until then, the use of graft in the posterior vaginal wall should generally be avoided.

Last, sacrocolpoperineopexy is a modification of sacrocolpopexy. It may be selected for correction of posterior vaginal wall descent when an abdominal approach is employed for other prolapse procedures or if treatment of perineal descent is necessary (Cundiff, 1997; Lyons, 1997; Sullivan, 2001). With this procedure, the posterior sacrocolpopexy mesh is extended down the posterior vaginal wall to the perineal body. In several case series, anatomic cure rates exceeded 75 percent.

Perineum

The perineal body provides distal support to the posterior vaginal wall and anterior rectal wall and anchors these structures to the pelvic floor. A disrupted perineal body will allow descent of the distal vagina and rectum and will contribute to a widened genital hiatus.

To recreate normal anatomy, perineorrhaphy is often done in conjunction with posterior colporrhaphy (Chap. 45, p. 1122). During surgery, the perineum is rebuilt through midline plication of the perineal muscles and connective tissue. Importantly, overly aggressive plication can narrow the introitus, create a posterior vaginal wall ridge, and lead to entry dyspareunia. However, in a woman who is not sexually active, high perineorrhaphy with intentional introital narrowing is believed to lower the risk of posterior wall prolapse recurrence.

Mesh in Reconstructive Pelvic Surgery

Mesh Indications

Approximately 30 percent of women undergoing surgery for POP will require a repeat operation for recurrence (Olsen, 1997). To improve long-term outcomes of primary operations, surgeons may add synthetic mesh or biologic graft. A rationale for mesh use may include the need to bridge a space, weak or absent connective tissue, high recurrence risk, or comorbid connective tissue disease.

Synthetic mesh for sacrocolpopexy and for midurethral slings has been used for years, is widely studied, appears both safe and effective, and is considered standard of care. Mesh erosion develops in a small percentage of cases but can be managed with local estrogen therapy and limited vaginal wall mesh excision. Rarely is excision of the entire mesh warranted. Moreover, pelvic pain is rare after sacrocolpopexy or midurethral sling, and mesh is generally not implicated. Surgeons have also used biologic grafts for sacrocolpopexy and midurethral slings. However, these materials are associated with high rates of prolapse recurrence (FitzGerald, 1999, 2004; Gregory, 2005).

Synthetic mesh use for prolapse repair surgery expanded rapidly after the first mesh product specifically for transvaginal repair came to market in 2001. Unfortunately, widespread adoption of transvaginal mesh procedures followed but without long-term safety and efficacy data. A systematic review of the literature in 2008 found a lack of high-quality data (Sung, 2008). More recently, a Cochrane review of 10 trials comparing transvaginal mesh with native tissue repair found that mesh reduced the risk of recurrent anterior vaginal wall prolapse and prolapse symptoms (Maher, 2016). However, the mesh erosion rate was significantly higher. Other adverse associations, which can be irreversible, included scarring, pain, and dyspareunia.

In 2011, the Food and Drug Administration (FDA) updated a public health warning to state that mesh-related complications were more serious than previously noted and were not rare. After this warning, the use of mesh for prolapse repair declined sharply (Sammarco, 2018). Subsequently, the FDA ordered mesh manufacturers to perform studies comparing transvaginal mesh–augmented repair against native tissue repair. However, prior to the conclusion of these studies, the FDA (2019) determined that it had not received sufficient evidence regarding transvaginal mesh's safety and efficacy or its superiority to native tissue. Manufacturers were required to immediately halt sales of their mesh products. Although free mesh is still available, there are no FDA-approved surgical mesh products intended for the use in the transvaginal repair of prolapse. Importantly, this does not include the use of synthetic mesh for sacrocolpopexy or midurethral sling.

As a result of the FDA action, synthetic mesh should not be routinely used in transvaginal prolapse repairs. However, for some high-risk individuals, benefits may outweigh risks. Candidates may include those with recurrent prolapse, with an unacceptable risk of failure using non-mesh approaches, or with specific medical comorbidities that preclude a lengthier alternative repair. Only experienced prolapse surgeons should perform these repairs and only after a careful discussion in which risks and benefits are presented. The American College of Obstetricians and Gynecologists (2019b) and American Urogynecologic Society (2019) echo these concerns. They recommend that transvaginal synthetic mesh for POP repair be reserved for high-risk women in whom benefits outweigh risks.

TABLE 24-7. Types of Surgical Mesh

Type I:	Macroporous. Pore size >75 μm (size required for infiltration by macrophages, fibroblasts, blood vessels in angiogenesis, and collagen fibers) *GyneMesh, Atrium, Marlex, Prolene*
Type II:	Microporous. Pore size <10 μm in at least 1 dimension *Gore-Tex*
Type III:	Macroporous patch w/multifilaments or a microporous component *Teflon, Mersilene, Surgipro, Mycro Mesh*
Type IV:	Submicronic. Pore size <1 μm. Often used in association with type I mesh for intraperitoneal adhesion prevention *Silastic, Cellgard, Preclude*

Mesh Material

Surgeons using mesh or grafts should be familiar with the different types and their characteristics. Biologic grafts may be autologous, allograft, or xenograft. *Autologous grafts* are harvested from another part of the patient's body such as rectus abdominis fascia or fascia lata of the thigh. Morbidity is low but may include longer operative time, pain, hematoma, or weakened fascia at the harvest site. *Allografts* come from a human source other than the patient and include cadaveric fascia or cadaveric dermis. *Xenografts* are biologic tissue obtained from a source or species foreign to the patient such as porcine dermis, porcine small intestinal submucosa, or bovine pericardium. Biologic materials have varying biomechanical properties and, as noted earlier, are associated with high rates of prolapse recurrence. Thus, recommendations on the appropriate clinical situations for biologic material are limited.

Synthetic mesh is classified as types I through IV, based on pore size (Table 24-7) (Amid, 1997). Pore size is the most important property of synthetic mesh. Bacteria generally measure less than 1 μm, whereas granulocytes and macrophages are typically larger than 10 μm. Thus, a mesh with pore size <10 μm may allow bacterial but not macrophage infiltration and thereby predispose to infection. Accordingly, type I mesh has the lowest rate of infection compared with types II and III. Pore size is also the basis of tissue ingrowth, angiogenesis, flexibility, and strength. Pore sizes of 50 to 200 μm allow for superior tissue ingrowth and collagen infiltration. This again favors type I. Meshes are either monofilament or multifilament. Multifilament mesh has small intrafiber pores that can harbor bacteria, therefore, monofilament mesh is recommended. From these findings, consensus suggests that if synthetic mesh is used, type I monofilament is the best choice for reconstructive pelvic surgery.

Concomitant Prolapse and Incontinence Surgery

Prior to POP repairs, women should be evaluated for SUI (Chap. 23, p. 521). Those with bothersome SUI symptoms are considered for concurrent antiincontinence surgery. However, in women without SUI symptoms, latent stress incontinence may be unmasked or SUI may develop de novo following prolapse repair. Therefore, preoperative urodynamic testing with the prolapse replaced is recommended. If SUI is demonstrated, these patients are also considered for a concurrent antiincontinence operation. This has been a difficult decision for patients and surgeons because a procedure with known risks is being performed for a problem that does not currently exist and may never develop.

The CARE (Colpopexy and Urinary Reduction Efforts) trial has added clarity (Brubaker, 2006). In this randomized trial, women undergoing abdominal sacrocolpopexy for prolapse who did not exhibit symptoms of SUI were randomly assigned to undergo concurrent Burch colposuspension or not. Three months after surgery, 24 percent of women in the Burch group and 44 percent of women in the control group met one or more criteria for SUI. The incontinence was bothersome in 6 percent of the Burch group and 24 percent of the control group.

These data can be interpreted in several ways. It can be argued that all women undergoing sacrocolpopexy for stage 2 or greater anterior vaginal wall prolapse should undergo Burch colposuspension, as 44 percent will develop SUI symptoms. However, the opposing argument is that only 24 percent will develop bothersome incontinence symptoms, thus three quarters of women would be subjected to an unnecessary operation.

In a similar trial, the Outcomes Following Vaginal Prolapse Repair and Mid Urethral Sling (OPUS) trial, women undergoing vaginal surgery for POP who did not have SUI symptoms were randomly assigned to receive a midurethral sling or sham incision. Twelve months after surgery, 27 percent of women in the sling group and 43 percent of women in the sham group had incontinence (Wei, 2012).

Importantly, these studies provide high-quality evidence for a surgeon to share during patient counseling. The decision to perform a concurrent antiincontinence operation in women without SUI should be individualized and based on risks, benefits, and patient goals and expectations.

Obliterative Procedures

Obliterative approaches for pronounced POP include LeFort colpocleisis and complete colpocleisis (Chap. 45, p. 1145). Performed in women with or without prior hysterectomy, these procedures involve removing vaginal epithelium, suturing anterior and posterior vaginal walls together, obliterating the vaginal vault, and effectively closing the vagina. Obliterative procedures are appropriate only for elderly or medically compromised patients with no desire for future coital activity.

Obliterative procedures are technically easier, require less operative time, and offer superior success rates compared with reconstructive procedures. Success rates for colpocleisis range from 91 to 100 percent, although the quality of evidence-based studies supporting these rates is poor (FitzGerald, 2006). After colpocleisis, fewer than 10 percent of patients express regret, which is often due to loss of coital activity (FitzGerald, 2006; Wheeler, 2005). Thus, the surgical counseling process must include an honest and thoughtful discussion with the patient and her partner regarding future sexual intercourse. Latent SUI can be unmasked with colpocleisis due to downward traction on the urethra. However, the morbidity of a concurrent antiincontinence procedure may outweigh the potential incontinence risk and is considered before adding surgeries in women who may already be medically compromised.

In patients with a uterus, vaginal hysterectomy may be performed prior to colpocleisis. However, concurrent hysterectomy increases blood loss and operative time (von Pechmann, 2003). Again, in compromised patients, this can negate some of the benefits of colpocleisis. If uterine retention is planned, neoplasia is excluded preoperatively. For this, Pap testing should be current, and interrogation of the endometrium is performed.

ANAL INCONTINENCE

Although definitions are inconsistent, anal incontinence (AI) is most commonly defined as an involuntary loss of flatus, mucus, or fecal material that causes a social or hygienic problem (Abrams, 2018; Sultan, 2017). The definition of AI includes incontinence of flatus, whereas that of fecal incontinence (FI) does not. From a consensus workshop, a more patient-centered term "accidental bowel leakage" was suggested for communication with patients (Bharucha, 2015).

AI can lead to poor self-image and isolation, and the social and quality-of-life effects of AI are significant (Johanson, 1996). Additionally, AI raises the likelihood that an older patient will be admitted to a nursing home rather than cared for at home (Grover, 2010).

Epidemiology

AI is common. From one national survey, the prevalence of FI in women approximated 9 percent using 2005 through 2010 data (Wu, 2014). Of affected individuals, liquid stool incontinence was noted in 6.2 percent, mucus in 3.1 percent, and solid stool in 1.6 percent (Whitehead, 2009). The prevalence of FI rose from 2.6 percent in those aged 20 to 30 years to 15.3 percent in subjects aged 70 years or older. In older, institutionalized women, AI prevalence may reach 46 percent (Nelson, 1998). Notably, FI is also not significantly associated with race or ethnicity, education level, income, or marital status (Whitehead, 2009).

Physiology

Normal defecation and anal continence are complex processes that require: (1) a competent anal sphincter complex, (2) normal anorectal sensation, (3) adequate rectal capacity and compliance, and (4) conscious control. Logically, mechanisms responsible for FI include anal sphincter and pelvic floor weakness, reduced or enhanced rectal sensation, diminished rectal capacity and compliance, and diarrhea (Bharucha, 2015). In many patients, these factors are additive.

Muscular Contributions

Essential contributors to fecal continence include the internal and external anal sphincters and the puborectalis muscle (Figs. 38-9 and 38-21, p. 799). The internal anal sphincter (IAS) is the thickened distal 3- to 4-cm longitudinal extension of the colon's circular smooth-muscle layer. It is innervated by the autonomic nervous system and provides 70 to 85 percent of the anal canal's resting pressure (Frenckner, 1975). As a result, the IAS contributes substantially to the maintenance of fecal continence at rest.

The external anal sphincter (EAS) consists of striated muscle and is primarily innervated by somatic motor fibers that course in the inferior anal (rectal) branch of the pudendal nerve (Fig. 25-1A). The EAS provides the anal canal's squeeze pressure and is mainly responsible for maintaining fecal continence when continence is threatened. At times, squeeze pressure may be voluntary or may be induced by increased intraabdominal pressure. In addition, although resting sphincter tone is generally attributed to the IAS, the EAS maintains a constant state of resting contraction and may be responsible for approximately 25 percent of the anal canal's resting pressure. During defecation, however, the EAS relaxes to allow stool passage.

The puborectalis muscle is part of the levator ani muscle and is innervated from its pelvic surface by direct efferents from the third, fourth, and fifth sacral nerve roots (see Fig. 25-1B) (Barber, 2002). Although disputed, it may also be innervated from its perineal surface by the inferior rectal branch of the pudendal nerve. Its constant tone contributes to the anorectal angle, which aids in preventing rectal contents from entering the anus (Fig. 38-10, p. 800). Similar to the EAS, this muscle can be contracted voluntarily or in response to sudden increases in abdominal pressure.

The role of the puborectalis in maintaining stool continence remains controversial. However, it is best appreciated in women who remain continent of solid stool despite anal sphincter defects (Fig. 25-2). Moreover, atrophy of this muscle has been associated with FI (Bharucha, 2004). With normal puborectalis relaxation, evacuation is generally aided by the better longitudinal alignment of the rectoanal lumen. Conversely, paradoxical contraction of the puborectalis muscle during defecation may lead to impaired evacuation.

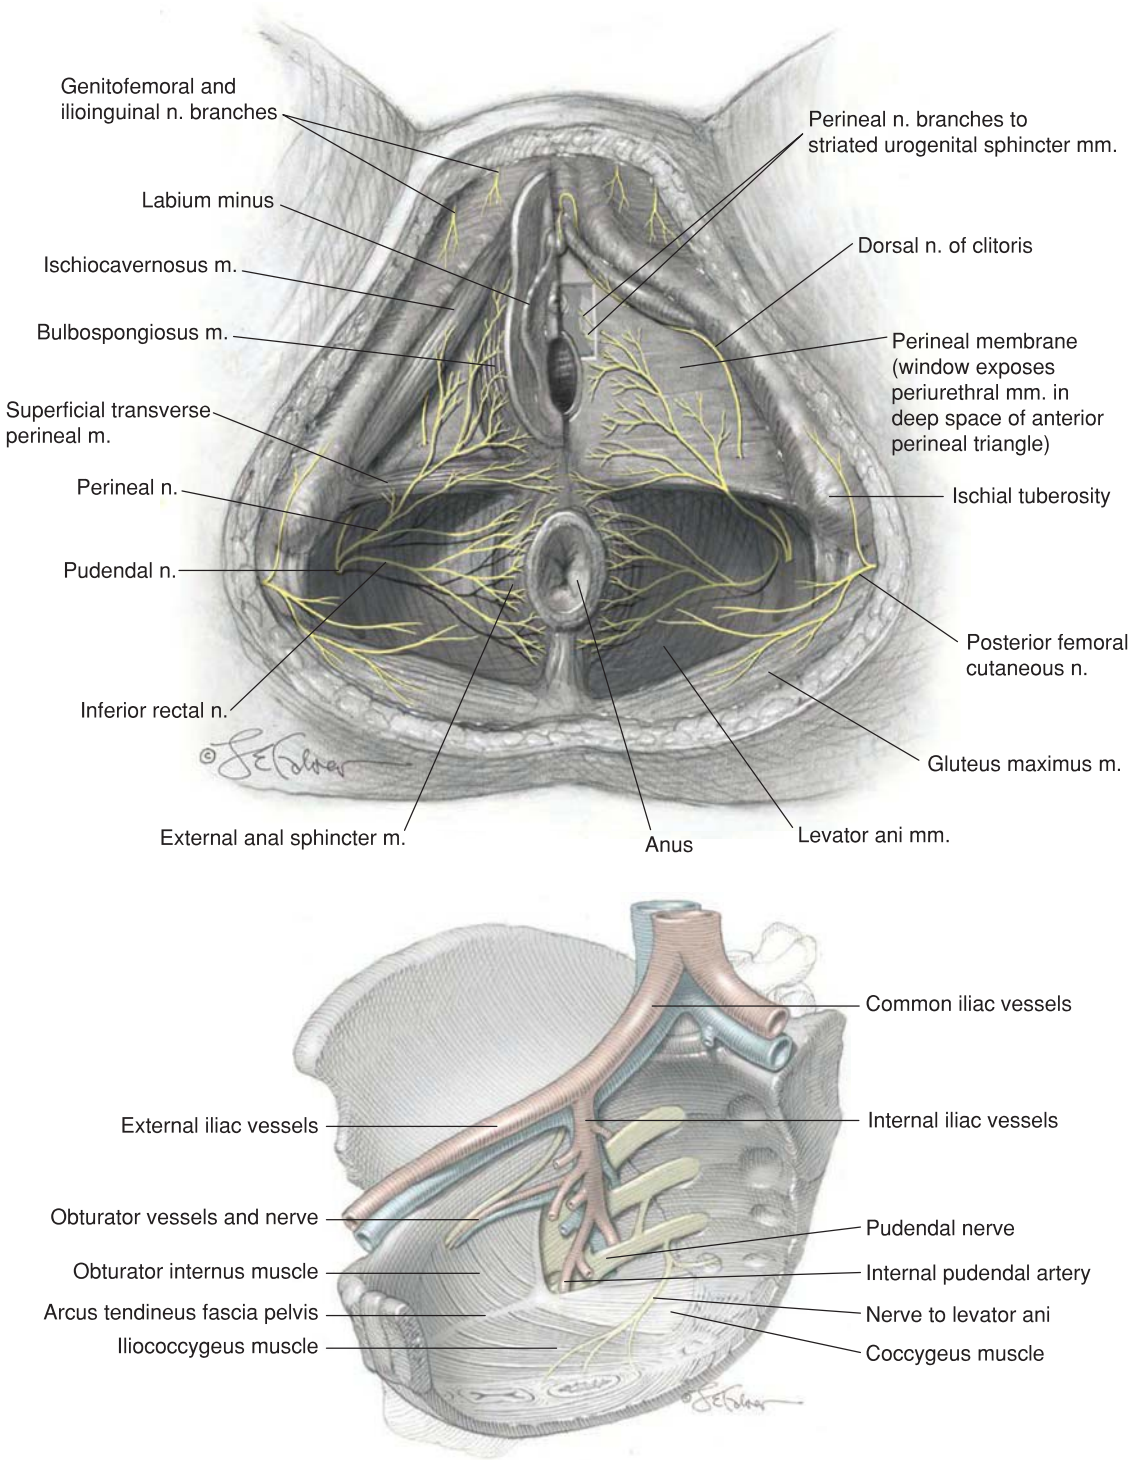

FIGURE 25-1 Innervation of the anal sphincter complex. **A.** The external anal sphincter is innervated by the inferior rectal branch of pudendal nerve. **B.** Innervation of the female pelvic floor muscles from direct branches of S3–S5.

Anorectal Sensation

Innervation to the rectum and anus is derived from intrinsic nerves present in the rectoanal wall and from the inferior hypogastric nerve plexus, which contains sympathetic and parasympathetic components (Fig. 38-13, p. 802). In addition, the inferior rectal branch of the pudendal nerve conveys sensory input from the lower anal canal and the skin around the anus. Sensory receptors within the anal canal and pelvic floor muscles can detect the presence of stool in the rectum and the degree of distention. Through these neural pathways, information regarding rectal distention and contents are transmitted and processed. With this, sphincter action can be coordinated.

The rectoanal inhibitory reflex (RAIR) refers to the transient relaxation of the IAS and contraction of EAS induced by rectal distention when stool first arrives in the rectum. This reflex is

FIGURE 25-2 Chronic fourth-degree laceration with complete absence of the perineal body and the anterior portion of external anal sphincter (cloacal-like deformity).

mediated by the intrinsic nerves in the rectoanal wall and allows the sensory-rich upper anal canal to come in contact with or "sample" the rectal contents (Whitehead, 1987). Specifically, the IAS relaxes to allow the anal epithelium to ascertain whether rectal contents are gas, liquid, or solid stools (Miller, 1988).

Following integration of this neural information, defecation can ensue in the appropriate social setting. Alternatively, if required, defecation can generally be postponed, as the rectum can accommodate its contents and the EAS or puborectalis muscle or both can be voluntarily contracted. However, if rectal sensation is impaired, contents may enter the anal canal and may leak before the EAS can contract (Buser, 1986).

Evaluation of the RAIR may clarify the underlying etiology of AI in some patients. As examples, this reflex is absent in those with congenital aganglionosis (Hirschsprung disease) but preserved in patients with cauda equina lesions or after spinal cord transection (Bharucha, 2006).

Rectal Accommodation and Compliance

Following anal sampling, the rectum can relax to admit the increased rectal volume in a process known as *accommodation*. The rectum is a highly compliant reservoir that permits stool storage. As rectal volume rises, an urge to defecate is perceived. If this urge is voluntarily suppressed, the rectum relaxes to continue stool accommodation. A loss of rectal compliance may decrease the ability of the rectal wall to stretch or accommodate, and as a result, rectal pressure may remain high. This may place greater demands on the other components of the continence mechanism such as the anal sphincter complex.

Rectal compliance can be calculated by measuring the pressure sensitivity to and maximal volume tolerated from a fluid-filled balloon during anorectal manometry. Rectal compliance may be diminished in those with ulcerative and radiation proctitis. In contrast, greater compliance may be noted in certain patients with chronic constipation. An extreme rare example is megarectum, in which the rectum can hold ≥1500 mL of stool.

Incontinence Risks

Obstetric

Abnormal defecation develops if components of anal continence are altered (Table 25-1). In younger, reproductive-aged women, the most common association with AI is vaginal delivery and damage to the anal sphincter muscles (Snooks, 1985; Sultan, 1993). This damage may be mechanical or neuropathic. Interestingly, the incidence of FI following vaginal delivery has declined from 13 percent of primiparas two decades ago to 8 percent in more recent series (Bharucha, 2015). This may reflect fewer instrumented vaginal deliveries and a more restricted use of episiotomy.

Rates of sphincter tear during vaginal births in the United States range from 6 to 18 percent (Fenner, 2003; Handa, 2001). In one study of primiparas delivered at term, at both 6 weeks and 6 months postpartum, women who sustained anal sphincter tears during vaginal delivery had twice the risk of FI and reported more severe FI compared with women who delivered vaginally without evidence of sphincter disruption (Borello-France, 2006). However, a retrospective study of 151 women who delivered 30 years previously reported that women with a prior sphincter disruption were more likely to have

TABLE 25-1. Risk Factors for Fecal Incontinence

Obstetric	
Increasing parity	Anal sphincter damage
Medical conditions	
Obesity	Diabetes mellitus
Aging	COPD
Smoking	CHTN
Postmenopausal	Stroke
Medications	Scleroderma
Decreased activity	Pelvic radiation
Urogynecologic	
Urinary incontinence	Pelvic organ prolapse
Gastrointestinal	
Constipation	Anal abscess
Diarrhea	Anal fistula
Fecal urgency	Anal surgery
Food intolerance	Cholecystectomy
IBS	Rectal prolapse
Neuropsychiatric	
Spinal cord lesion	Myopathies
Parkinson disease	Psychosis
Spinal surgery	Nerve stretch injury
Multiple sclerosis	Cognitive dysfunction
Brain tumor	

COPD = chronic obstructive pulmonary disease.
CHTN = chronic hypertension; IBD = irritable bowel disease; IBS = inflammatory bowel disease.

"bothersome" flatal incontinence but were not at greater risk for FI compared with women who had a simple episiotomy or who underwent cesarean delivery (Nygaard, 1997). Thus, other mechanisms associated with pregnancy and with aging may contribute to AI regardless of delivery mode or anal sphincter disruption. Importantly, cesarean delivery minimizes the risk of anatomic anal sphincter injury, but it does not universally protect against later AI. The National Institutes of Health (NIH) (2006) consensus conference on cesarean delivery on maternal request concluded that evidence was insufficient to support a practice of elective cesarean delivery for the prevention of pelvic floor disorders, including FI.

Other Factors

Few epidemiologic studies have evaluated the risk factors for FI in the community. Underlying bowel disturbances, particularly diarrhea; the symptom of rectal urgency; and comorbid chronic illness are the strongest independent factors (Bharucha, 2010, 2015). Liquid stool is more difficult to control than solid, and thus FI may develop even if all components of the continence mechanism are grossly intact. Alternatively, chronic constipation with straining to defecate may damage the muscular and/or neural components of the sphincter mechanism. Similarly, other neuromuscular injury to the puborectalis and/or anal sphincter muscles, such as that associated with pelvic organ prolapse, may lead to AI.

Radiation therapy involving the rectum can result in poor compliance and loss of accommodation. Also, nervous system dysfunction in those with spinal cord injury, back surgery, multiple sclerosis, diabetes, or cerebrovascular accident may impair accommodation, sensation, reflexes, and muscle function. Finally, loss of rectal sensation and lower squeeze sphincter pressures can be seen with normal aging. One study suggests that even asymptomatic older nulliparas have anal sphincter neurogenic injury, which partly explained weak anal squeeze pressures (Bharucha, 2012).

Diagnosis

Barriers to care include embarrassment, perception that FI is a normal part of aging, fear that it might reflect a cancer or other serious disorder, and unfamiliarity or pessimism regarding treatment options (Brown, 2017). In one study that evaluated women presenting for benign gynecologic care, only 17 percent with FI were asked about the symptom by their health-care provider (Boreham, 2005).

No classification for FI is widely accepted. However, the type (urge, passive, or mixed), etiology, and severity provide some basis to categorize FI.

History

During this process, specific questions are posed regarding incontinence duration and frequency, stool consistency, timing of incontinent episodes, use of sanitary protection, and incontinence-related social impairment. Risk factors noted in Table 25-1 are sought. Importantly, urge-related AI is differentiated from incontinence without awareness. For example, urgency without incontinence may reflect inability of the rectal reservoir to store stool rather than a sphincteric disorder.

Validated questionnaires, stooling diaries, and the Bristol Stool Scale are objective options. Of these, a patient diary of stool habits is commonly used in research, but its utility is often limited by poor patient adherence. Instead, validated questionnaires provide objective scoring of incontinence. Four often-used symptom severity scores are the Pescatori Incontinence Score, Wexner (Cleveland Clinic) Score, St. Mark's (Vaizey) Score, and Fecal Incontinence Severity Index (FISI) (Table 25-2) (Jorge, 1993; Pescatori, 1992; Rockwood, 1999; Vaizey, 1999). All of these incorporate the type and

TABLE 25-2. St. Mark's (Vaizey) Incontinence Score

	Never[a]	Rarely[b]	Sometimes[c]	Weekly[d]	Daily[e]
Incontinence for solid stool	0	1	2	3	4
Incontinence for liquid stool	0	1	2	3	4
Incontinence for gas	0	1	2	3	4
Alteration in lifestyle	0	1	2	3	4
		No	Yes		
Need to wear a pad or plug		0	2		
Taking constipating medicines		0	2		
Lack of ability to defer defecation for 15 minutes		0	4		

[a]Never = no episodes in the past 4 weeks.
[b]Rarely = 1 episode in the past 4 weeks.
[c]Sometimes = >1 episode in the past 4 weeks but <1 a week.
[d]Weekly = 1 or more episodes a week but <1 daily.
[e]Daily = 1 or more episodes daily.
Add one score from each row: minimum score = 0 = perfect continence; maximum score = 24 = totally incontinent.
From Vaizey, 1999, with permission.

TABLE 25-3. Fecal Incontinence Quality of Life Scale Composition

Scale 1: Lifestyle	
I am afraid to go out	I avoid traveling
I avoid visiting friends	I avoid traveling by plane or train
I avoid many things I want to do	I avoid staying overnight away from home
I plan my schedule around my bowel pattern	I avoid going out to eat
It is difficult for me to get out and do things	I limit how much I eat before I go out
Scale 2: Coping/Behavior	
I feel I have no control over my bowels	I have sex less often than I would like to
I worry about bowel accidents	I worry about not reaching the toilet in time
The possibility of bowel accidents is always on my mind	
Whenever I go someplace new, I specifically locate where the bathrooms are	
I try to prevent bowel accidents by staying very near a bathroom	
I can't hold my bowel movement long enough to get to the bathroom	
Whenever I am away from home, I try to stay near a restroom as much as possible	
Scale 3: Depression/Self-Perception	
In general, how would you say your health is?	I feel different from other people
I am afraid to have sex	I enjoy life less
I feel depressed	I feel like I am not a healthy person
During the past month, have you felt so sad, discouraged, hopeless, or had so many problems that you wondered if anything was worthwhile?	
Scale 4: Embarrassment	
I leak stool without even knowing it	
I worry about others smelling stool on me	
I feel ashamed	

Adapted from Rockwood, 2000, with permission.

frequency of leakage. The Vaizey Score and the FISI include symptom weighting. In the FISI, inclusion of patient-assigned severity scores enhances its utility compared with other scales. The ability of the Vaizey Score to incorporate a component of fecal urgency makes this scale desirable in certain clinical trials.

The patient's quality-of-life decline from AI is also characterized. The validated fecal incontinence quality-of-life (FI-QOL) questionnaire is a 29-item tool designed to estimate associated worsening lifestyle, coping behavior, depression/self-perception, and embarrassment (Table 25-3) (Rockwood, 2000). Other quality-of-life scales available include the Modified Manchester Health Questionnaire and the Gastrointestinal Quality of Life Index (Kwon, 2005; Sailer, 1998). These validated tools may be used to diagnose AI and then to follow treatment response.

Last, the Bristol Stool Scale is often selected to determine a patient's usual stool consistency (Lewis, 1997). This validated scale contains seven descriptions and pictures of stool types (Fig. 25-3) (Degen, 1996). Such stool consistency categorization correlates with objective measures of whole-gut transit time (Heaton, 1994).

Physical Examination

This begins with careful inspection of the anus and perineum to identify stool soiling, scars, perineal body length, hemorrhoids, rectal prolapse, dovetail sign, or other anatomic abnormalities (Fig. 25-4). The perianal skin is gently stroked with a cotton-tipped swab to obtain the cutaneous anal reflex. Colloquially termed *anal wink*, circumferential contraction of the anal skin and underlying EAS is normally seen. This finding provides gross assessment of pudendal nerve integrity.

With digital rectal examination, one can assess anal resting tone, sample for gross or occult blood, palpate masses or low fecal impaction, and inspect for fistula. Squeeze pressure can subjectively be judged during voluntary patient contraction of the EAS around a gloved finger inserted into the anorectum. Last, during patient Valsalva maneuver, one observes for excessive perineal body descent, vaginal wall prolapse, rectal prolapse, or muscle incoordination (Fig. 25-5). With the last, a paradoxic contraction—that is, abnormal sphincter and/or puborectalis muscle contraction around the finger—may be elicited during patient Valsalva when an examining finger is inserted into the anorectum. To identify dyssynergia, digital rectal examination is reasonably accurate relative to manometry for assessing anal resting tone and squeeze function (Orkin, 2010; Tantiphlachiva, 2010).

Initial history and examination typically guide testing, which may include imaging and functional studies, described next. In some cases, barium enema or colonoscopy may be indicated to exclude inflammatory bowel conditions or malignancy.

Diagnostic Testing

Anorectal Manometry. Women with persistent symptoms despite conservative measures described later are best served by specialist referral and anorectal testing (p. 566). Anorectal

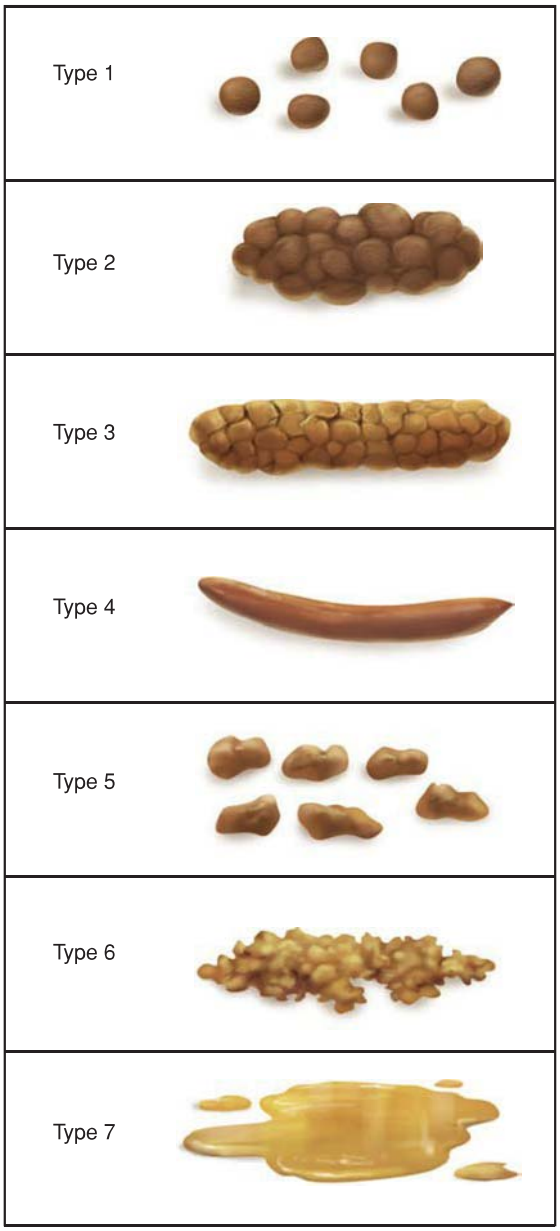

FIGURE 25-3 Bristol Stool Scale. Stools are categorized by their shape and texture.

manometry is an initial step and followed, if necessary, by anorectal imaging.

Anorectal manometry is a simple test performed mainly in academic institutions with an anophysiology laboratory. Manometry provides objective assessment of: (1) rectal compliance and rectal sensation, (2) reflexes, and (3) anal sphincter function (Table 25-4). During this test, a small flexible tube containing an inflatable balloon tip and pressure transducer is inserted into the rectum (Fig. 25-6). First, rectal compliance and sensation may be determined by sequentially inflating a rectal balloon to various volumes. Poor rectal compliance may be noted by an inability to inflate a balloon to typical volumes without patient discomfort. This may indicate a rectal reservoir that is unable to appropriately store stool. In contrast, decreased perception of balloon insufflation may indicate neuropathy.

FIGURE 25-4 Photograph showing the "dovetail" sign, which is created by disruption of the anterior portion of external anal sphincter (EAS). Radial skin spikes are typically formed by attachment of skin to the EAS but are commonly absent from 10 to 2 o'clock (*asterisks*) in those with this disruption.

Second, sphincter reflexes are also assessed during pressure measurements. During balloon insufflation, relaxation of the IAS should accompany rectal distention via the RAIR, described earlier (p. 559).

Third, IAS resting pressure and EAS squeeze pressure are then measured at incremental points as the balloon is slowly withdrawn from the rectum. In general, lower pressure readings may indicate structural disruption, myopathy, or neuropathy. As an additional test, the rectal balloon expulsion test may be performed as a patient simulates defecation and expels the balloon. The balloon expulsion test is mainly used in patients with constipation, and it attempts to differentiate between obstructed constipation and functional constipation (Minguez, 2004).

FIGURE 25-5 During patient Valsalva, a full-thickness rectal prolapse protrudes through the anal opening.

TABLE 25-4. Functional Testing for Patients with Fecal Incontinence[a]

Factors	Manometry				DG	EAUS	MRI	EMG

Reservoir			+	+	+			
Megarectum			+		+		+	
Pelvic floor								
Perineal descent					+		+	
Anorectal angle					+		+	
Neural								
Pudendal nerve		+						+

[a]Plus sign indicates an appropriate test for a particular component of continence.
DG = defecography; EAS = external anal sphincter; EAUS = endoanal ultrasonography; EMG = electromyography; IAS = internal anal sphincter; MRI = magnetic resonance imaging; RC = rectal compliance; RP = rectal perception.

However, manometry has poor specificity. For example, high-resolution catheter manometry (HRM), introduced in 2008, demonstrates that patterns previously regarded as abnormal are also observed in most healthy patients (Basilisco, 2017). Despite this, anal manometry results can bolster results of other testing to help support a diagnosis.

Endoanal Ultrasonography. Also known as *transanal sonography*, endoanal sonography (EAUS) is now the primary diagnostic imaging technique to evaluate the integrity, thickness, and length of the IAS and EAS (Fig. 25-7). The technique uses a rotating endoprobe with a ≥10-MHz transducer, which provides a 360-degree evaluation of the anal canal. Sonographic gel is placed on the probe tip, which is sheathed with a condom prior to insertion into the anus.

This modality can also image the puborectalis muscle and perineal body. In one study of incontinent women, perineal body thickness <10 mm was associated with anal sphincter defects in 97 percent of cases, whereas perineal body thicknesses of 10 to 12 mm were associated with sphincter defects in only one third of patients (Oberwalder, 2004). Perineal body thickness >12 mm was infrequently associated with these defects.

Other techniques also may be informative. For example, dynamic endoanal or transperineal sonography can permit functional assessment of the anorectum, similar to defecography, described next (Vitton, 2011).

Evacuation Proctography. During this radiographic test, also known as barium defecography, the rectum is opacified with barium. A thick barium paste is placed in the vagina, and

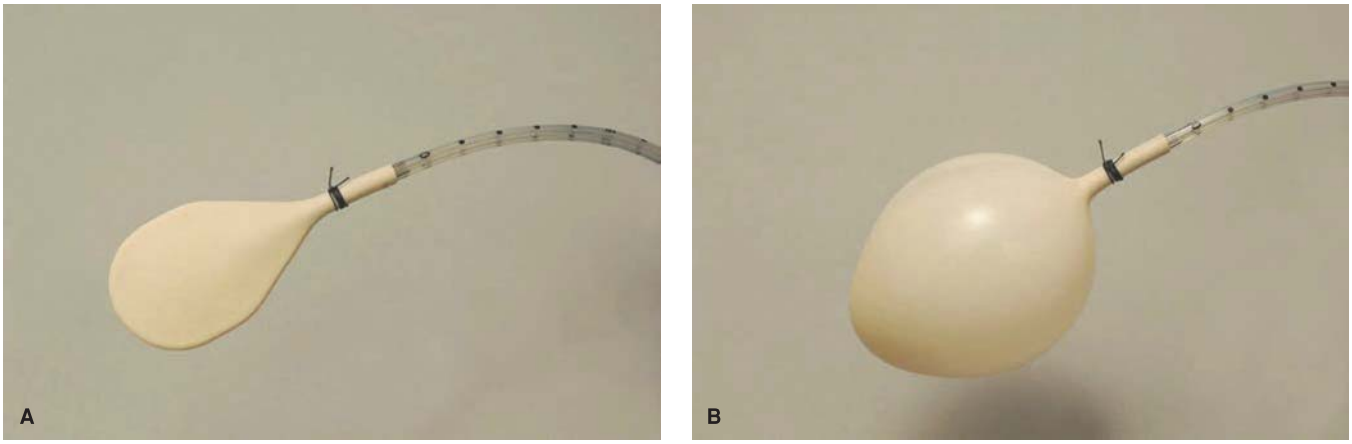

FIGURE 25-6 Manometry tube and balloon, empty **(A)** and after filling **(B)**.

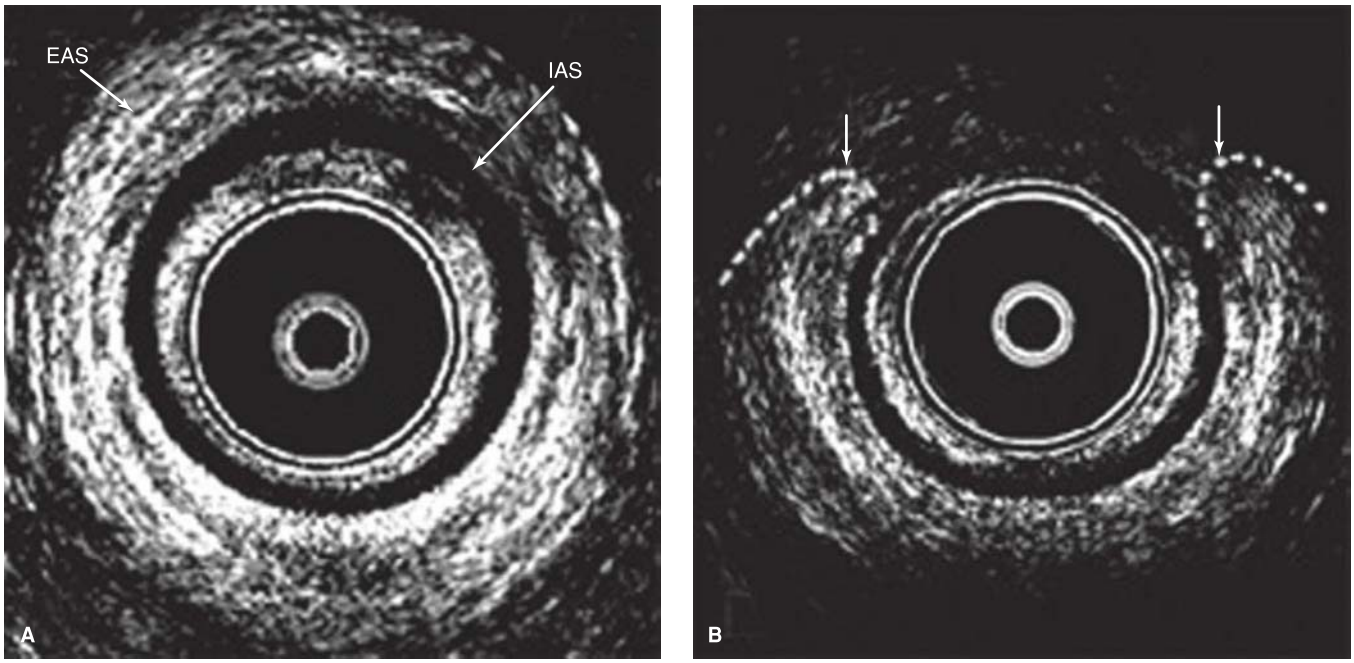

FIGURE 25-7 Cross-sectional anal endosonography images at level of mid anal canal. **A.** A woman with normal anal sphincters. **B.** Anterior defects of the external and internal anal sphincter muscles. EAS = external anal sphincter; IAS = internal anal sphincter. Dashed lines and arrows in B illustrate the ends of the torn EAS.

the small bowel is opacified by an oral barium suspension. Seated on a commode, the patient undergoes radiographic or fluoroscopic imaging while resting, contracting her sphincter, coughing, and straining to expel the barium. Both anorectal anatomy and the mechanics of defecation can be assessed. This test is not widely used to assess evacuation disorders unless obstructive causes for AI are suspected. Accordingly, it may be obtained if intussusception, internal rectal prolapse, enterocele, or failed relaxation of the puborectalis muscle during defecation is a concern.

Magnetic Resonance Imaging. Magnetic resonance (MR) imaging of the anal sphincter complex can be done either with an endoanal coil placed in the anorectum or with external phased-array coils. This latter external coil technique is preferred because physical anatomy is less distorted and the lack of an intraluminal coil aids patient comfort (Van Koughnett, 2013a). MR imaging is more expensive than EAUS, and its value for anal sphincter evaluation is controversial. First, EAUS is more sensitive in detecting IAS abnormalities, whereas MR imaging is more sensitive in defining EAS morphology, including atrophy (Beets-Tan, 2001; Rociu, 1999). This may have value preoperatively, as patients with EAS atrophy may have poorer results following anal sphincteroplasty compared with those without atrophy (Briel, 1999). Second, MR imaging results vary considerably among interpreters and their experience level. Thus, either EAUS or MR imaging can be recommended only if sufficient experience is available (Terra, 2006).

Another MR imaging modality, termed *dynamic MR imaging*, allows dynamic examination of rectal emptying and evaluation of pelvic floor muscles during rest, squeeze, and defecation (Gearhart, 2004; Kaufman, 2001). Thus, it simultaneously permits a survey of pelvic anatomy, organ prolapse, and defecatory function. This may be particularly appealing to patients requiring multiple anorectal tests (Khatri, 2014; Van Koughnett, 2013a). However, it is technically difficult, more expensive, and again requires an experienced radiologist. Moreover, other than avoiding the ionizing radiation of evacuation proctography, this technique offers no advantage for studying rectal function. In addition, the variability of pelvic MR imaging measurements among readers is high (Lockhart, 2008). Despite these limitations, this test has been increasingly adopted in many academic settings, including our institution. Findings from a recent study provide normal values for anal sphincter and pelvic floor anatomy and function in asymptomatic healthy women (Tirumanisetty, 2018).

Electromyography. This test uses a needle or surface electrode to record electrical activity of muscles at rest and during contraction. During needle electromyography (EMG), needle electrodes are inserted through the skin into a muscle, and electrical activity detected by these electrodes is displayed graphically. Used mainly in research centers, EMG may be used to assess the neuromuscular integrity of the EAS and puborectalis muscle. Specifically, EMG can help clarify which portions of these muscles are contracting and relaxing appropriately. Additionally, following injury, muscle may be partially or completely denervated, and compensatory reinnervation may then follow. Patterns characteristic of such denervation and reinnervation can be identified with EMG.

Unlike needle electrodes, surface patch electrodes are placed on the darker-skinned area of the anus, cause little discomfort to the patient, and carry no risk of infection. However, this technique is prone to artifacts. In comparing the two, needle EMG is painful but provides useful information regarding sphincter innervation. Surface EMG may be best used during repetitive biofeedback sessions.

Pudendal Nerve Terminal Motor Latency Test. This stimulation test of the pudendal nerve measures the time delay between electrical nerve stimulation and EAS motor response. This delay, also termed *latency*, if prolonged, may indicate pudendal nerve pathology.

Although prolonged latency is a marker of idiopathic FI, this test provides little information regarding FI etiology. Moreover, pudendal nerve terminal motor latency (PNTML) results have been contradictory, and this test is not endorsed by many experts, including the American Gastroenterological Association (Diamant, 1999). Accordingly, PNTML has been replaced by more specific and sensitive tests for sphincter muscle innervation such as EMG (Barnett, 1999).

Newer and less invasive approaches for documenting neurogenic injury have been described (Carrington, 2018). The spinoanorectal pathways that govern anorectal neuronal function can be assessed using magnetic stimulation of the lumbar and sacral regions overlying these nerves. One study showed that translumbar and transsacral motor-evoked potentials of the rectum and anus provide better delineation of peripheral neuromuscular injury in individuals with fecal incontinence than PNTMLs (Rao, 2014). Although relatively easy to perform, this approach is not widely available.

Treatment

Nonsurgical Treatment

Treatment of FI is highly individualized. FI causes are often multifactorial, and treatments targeting only one mechanism are unlikely to benefit all patients. Moreover, because current surgical outcomes are less than optimal, most patients, even those with anatomic defects, are initially treated conservatively in a stepwise approach. This management may include patient education and normalization of stool consistency. Behavioral techniques are scheduled toileting attempts, purposeful sphincter contraction before coughing or lifting, and daily pelvic floor muscle exercises (Whitehead, 2015). Biofeedback is often recommended after conservative management fails.

Medical Management. For patients with minor incontinence, the use of bulking agents can improve stool consistency and create feces that are firmer and easier to control (Table 25-5). In support of this practice, a small randomized trial showed that fiber supplementation improved diarrhea-associated FI (Bliss, 2001). However, evidence that fiber supplements benefit patients with constipation-associated FI is lacking. Common side effects such as abdominal distention and bloating can be improved by starting with smaller doses or switching to a different agent.

To also bulk stool, agents that slow fecal intestinal transit time can reduce overall stool volume by lengthening the time available for the colon to reabsorb fluid from stool. Loperamide hydrochloride (Imodium) also raises anal resting tone and thus may even benefit patients with FI and no diarrhea (Read, 1982). Side effects are uncommon and include dry mouth.

Diphenoxylate hydrochloride (Lomotil) is used in the same capacity as loperamide, and dosing is similar. Although diphenoxylate is a Schedule V substance, potential for physical dependence is minimal.

Of other possible medications, amitriptyline is a tricyclic antidepressant that can be used to treat idiopathic FI. Although the mechanism of action is poorly understood, some benefits may be related to its anticholinergic properties. Cholestyramine and clonidine, an α-adrenergic agonist, also have been studied, but current data are limited (Whitehead, 2015). Last, the laxative lactulose aids some nursing home residents with FI associated with fecal impaction (Omar, 2013).

Bowel Management. Many patients with fecal seepage suffer from evacuation disorders, in which a large mass of solid stool fills the rectum and loose stool leaks around the obstruction (Rao, 2004). For some, evacuation disorders stem from underlying constipation. Instead, women with an evacuation disorder may have normal stool consistency. For these, anatomic defects, such as a rectocele, may trap stool. Others may have denervation and impaired rectal sensation.

For those with an underlying rectal evacuation disorder, pelvic floor biofeedback therapy is an option. Alternatively or in addition, rectal cleansing with a small enema or tap water reduces stool trapping. Daily, timed, tap-water enemas or glycerin or bisacodyl suppositories (Dulcolax) may be used to empty the rectum after eating. Bulking agents can be used concurrently with these evacuation methods to diminish stooling between desired defecations.

Pelvic Floor Muscle Strengthening. Also known as Kegel exercises, active pelvic floor muscle training (PFMT) exercises voluntary contract the levator ani muscles. Performance

TABLE 25-5. Medical Management of Fecal Incontinence

Treatment	Brand Name	Oral Dosage
Bulking agents		
Psyllium	Metamucil	1 tbsp. mixed into 8 oz. of water 1–3 times daily
Psyllium	Konsyl	1 tsp. mixed into 8 oz. of water 1–3 times daily
Methylcellulose	Citrucel	1 tbsp. mixed into 8 oz. of water 1–3 times daily
Loperamide hydrochloride	Imodium	2–4 mg, 1–4 times daily to a maximum daily dose of 16 mg
Diphenoxylate hydrochloride	Lomotil	5 mg, 1–4 times daily to a maximum daily dose of 20 mg
Amitriptyline	Generic	10–25 mg at bedtime; increase by 10–25 mg weekly up to 75–150 mg at bedtime or a therapeutic drug level

of these exercises is fully described in Chapter 23 (p. 527). Exercises are safe and inexpensive and may benefit patients with mild symptoms, especially if performed in conjunction with other early conservative interventions. However, these alone are less effective than biofeedback for patients with more severe FI symptoms (Heymen, 2009).

In contrast to active PFMT, anal musculature can be passively stimulated electrically by electrodes. However, when used as sole therapy, passive electrical stimulation of the anus appears to be ineffective (Whitehead, 2015).

Biofeedback and Pelvic Floor Therapy. Pelvic floor retraining with biofeedback therapy is recommended for patients with FI who do not respond to the conservative measures just outlined. Therapy goals aim to improve anal sphincter strength, sensory awareness of stool presence, and coordination between the rectum and the anal sphincter (Rao, 1998). The number and frequency of sessions required for improvement varies. Commonly, three to six 1-hour weekly or biweekly appointments are needed. In many cases, reinforcing sessions at various subsequent intervals are recommended.

Biofeedback is an effective treatment for FI, and up to 80 percent of treated patients show symptom improvement (Engel, 1974; Jensen, 1997; Norton, 2001). Despite this, one Cochrane review found insufficient evidence of biofeedback's benefits for FI (Norton, 2012). However, a randomized controlled trial by Heymen and coworkers (2009) offers support. These investigators initially provided education materials and instruction regarding fiber supplements and/or antidiarrheal medication. Patients who were adequately treated by these strategies (21 percent) were excluded from further study. The remaining 107 patients, who remained incontinent and dissatisfied, then progressed to treatment, either biofeedback or PFMT. Biofeedback training more effectively reduced FI severity and number of days with FI. Moreover, 3 months after training, 76 percent of biofeedback patients reported adequate relief of FI symptoms compared with only 41 percent of patients treated with PFMT. Twelve months later, biofeedback improvement persisted.

The results of this and other trials suggest that biofeedback may not be necessary for patients with milder FI symptoms. However, for those with more severe FI symptoms, instrument-assisted biofeedback is reasonable (Whitehead, 2015).

Minimally Invasive Procedures

Sacral Nerve Stimulation. In 2011, the FDA approved sacral nerve stimulation (SNS) for FI treatment. Also known as sacral neuromodulation, this surgery is typically offered to women who have failed to adequately improve with multiple other conservative therapies. A full description of the InterStim System procedure appears in Chapter 45 (p. 1111). To summarize, an electrode is placed near the S3 nerve root and is connected to a temporary pulse generator. Electrical charges to this nerve root may modulate abnormal afferent impulses (Gourcerol, 2011). Patients who show ≥50 percent improvement during the temporary test phase are eligible for a permanent pulse generator.

In one prospective trial, 90 percent of 133 patients proceeded from temporary to permanent stimulation (Wexner, 2010). Therapeutic success was defined as a 50-percent or greater reduction of incontinent episodes per week. At 12 months, 83 percent of subjects achieved therapeutic success, and 41 percent achieved 100-percent fecal continence. At 24 months, therapeutic success was found in 85 percent. At 5 years, 89 percent were deemed a therapeutic success, and 36 percent reported complete continence (Hull, 2013). Another recent study supports the long-term durability of SNS (Janssen, 2017). However, approximately 25 percent of the patients have undergone device removal because of complications and/or loss of efficacy.

For patients with an underlying EAS defect of up to 120 degrees, limited data suggest that SNS is also effective (Tjandra, 2008, Chan, 2008; Matzel, 2011). Although unclear, efficacy in these patients may be explained by retrograde propagated contractions in the colon induced by SNS. These contractions delay colonic transit and delivery of stool to the rectum (Patton, 2013). It is unclear whether sphincteroplasty may be necessary in such patients prior to an SNS procedure.

Percutaneous Tibial Nerve Stimulation. Because of the relative invasiveness and morbidity of SNS, other less invasive modalities have been tested for FI. Of these, percutaneous tibial nerve stimulation (PTNS) was tested because of its success for overactive bladder symptoms. The posterior tibial nerve contains fibers from the sacral nerves. Stimulation of its peripheral fibers transmits impulses to the sacral nerves and reflexively neuromodulates the rectum and anal sphincters (Shafik, 2003).

Supporting evidence is contradictory. One review of 13 studies showed that 62 to 82 percent of patients reported at least a 50-percent reduction in the frequency of FI episodes (Thomas, 2013). However, one randomized trial failed to show efficacy compared with sham treatment during a 12-week course (Knowles, 2015). A smaller sham-controlled study of PTNS found similar conclusions (van der Wilt, 2017). At present, PTNS is not recommended or FDA approved for FI treatment.

Bulking Agent Injection. Injecting inert substances around the anal canal in patients with FI aims to increase resting anal canal pressure (Shafik, 1993). Although many affected patients may be candidates for injectables, the ideal candidate is one who has seepage or mild to moderate FI, has failed medical management, and yet prefers to defer surgery (Van Koughnett, 2013b).

The results of a large randomized trial support the efficacy of *nonanimal stabilized hyaluronic acid/dextranomer (NASHA Dx)* injections compared with sham injections (Graf, 2011). The primary endpoint was a ≥50-percent decline in the number of incontinence episodes and a corresponding rise in incontinent-free days. A second injection was permitted in patients who did not improve within 1 month. At 3 months, 52 percent of the dextranomer-injected patients achieved the chosen endpoint compared with 31 percent of sham-treated patients. Notably, 80 percent of patients required a second injection. A surveillance study showed that benefits persisted for 36 months (Mellgren, 2014). NASHA Dx was approved by the FDA in 2012 and is now marketed as an office-based treatment.

Subsequent studies have questioned the efficacy of bulk injections and their mechanisms of action for FI (Dehli, 2013;

Rydingen, 2017). Thus, for any perianal bulking agent, future trial design should ideally define FI clinically and include anorectal measurements and meaningful clinical endpoints (Wald, 2018).

Radiofrequency Energy Delivery to Anal Canal. This FDA-approved outpatient procedure is currently used in some U.S. centers for refractory FI in patients without sphincter defects or pudendal neuropathy. It delivers radiofrequency energy to the IAS by means of a specifically designed anoscope. Resulting tissue heating is believed to cause collagen contraction followed by focal wound healing, remodeling, and tightening.

Small cohort studies show inconsistent or poor efficacy. Efron and colleagues (2003) found a median 70-percent resolution of symptoms in 50 patients. However, one retrospective series showed long-term benefit in only 22 percent, and most patients underwent additional treatments (Abbas, 2012). Moreover, one randomized trial of 40 patients showed no significant differences in treatment outcome, anal sphincter measurements, or quality-of-life scores at 6 months (Visscher, 2017).

Other Therapies. Of nonsurgical options, one vaginally inserted bowel-control device contains a silicone-coated stainless steel base and posteriorly directed balloon. Using a pump, the vaginal insert is inflated to occlude the adjacent rectum. Thus, its primary limitation is that not all women are successfully fitted. In one study, the device significantly improved objective and subjective measures of FI (Richter, 2015). Approximately 86 percent of patients considered bowel symptoms "very much better" or "much better." And, no serious adverse events were reported. However, long-term outcome data are needed.

Second, anally inserted devices or anal plugs present another nonsurgical option. However, most current devices are poorly tolerated (Deutekom, 2015).

Third, magnetic beads strung on an elastic band can be inserted surgically around the anal canal and beneath the skin to increase resting pressures. Overall experience with the device has been disappointing, and it is no longer actively marketed in the United States (Bartolotti, 2015).

Lastly, stem cell therapy is a promising approach that aims to regenerate damaged sphincter muscle by injection of autologous myoblasts. One Phase II, placebo-controlled, randomized study of 24 patients with FI showed a 58-percent response rate at 12 months in patients receiving treatment compared with an 8-percent rate in those assigned placebo (Boyer, 2018). However, resting or squeeze pressures did not differ. The reasons for improvement are unclear, but additional studies of this technique are awaited.

Surgical Treatment

Available FI surgical procedures provide less than optimal results and are associated with postoperative morbidity. Thus, surgery is reserved for those with major structural abnormalities of the anal sphincter(s), those with severe symptoms, and those who fail to respond to conservative management.

Anal Sphincteroplasty. Repair of the EAS and/or IAS is indicated for postpartum women with FI and an anterior sphincter defect from a recent obstetric injury. It may also be considered in patients with evidence of sphincter damage who present later with symptoms unresponsive to conservative measures. Others reserve sphincteroplasty for cases in which perianal bulking injection and SNS are not available or have proven unsuccessful (Bharucha, 2017).

Two methods may be used for sphincter repair and include an end-to-end technique and an overlapping method, both described in Chapter 45 (p. 1150). In patients remote from delivery, the overlapping technique is preferred by most colorectal surgeons and urogynecologists. With this, short-term continence improved 67 percent in one study (Madoff, 2004). However, during long-term postoperative surveillance, other reports show significant deterioration of continence (Bravo Gutierrez, 2004; Glasgow, 2012; Halverson, 2002). In a single, retrospective study, no patients remained completely continent to liquid and solid stool at 10 years (Zutshi, 2009). Hypotheses regarding this deterioration include aging, scarring, and progressive pudendal neuropathy related either to initial injury or to repair.

For chronic fourth-degree lacerations, also known as *cloacal-like deformities*, 46 percent of the 13 women in one study reported some form of anal incontinence at a mean of 7 years following surgery (Maldonado, 2019). The remainder was completely continent.

Patients who fail to improve after anal sphincteroplasty and who are found to have a persistent sphincter defect may be candidates for a second sphincteroplasty. However, those with an intact sphincter following repair and persistent symptoms are only considered candidates for conservative management or one of the minimally invasive surgical procedures described earlier.

At obstetric delivery, the overlapping method of anal sphincter repair does not provide superior results to those obtained with the traditional end-to-end method (Farrell, 2012; Fitzpatrick, 2000; Garcia, 2005). Moreover, overlapping repair requires greater technical skills and carries the potential for increased blood loss, operating time, and further pudendal nerve denervation injury. Thus, the end-to-end technique is likely to remain the standard method for sphincter reapproximation at delivery. Importantly, primary prevention of these lacerations should continue to be emphasized.

Bowel Diversion and Other Major Surgeries. Diversion is reserved for patients with incapacitating FI who fail other treatments (Chap. 46, p. 1217). For these selected patients, such procedures can significantly improve their quality of life.

Of other surgeries, gracilis muscle transposition is advocated for patients who have failed sphincter repair or those with a sphincter defect too large for muscle reapproximation (Baeten, 1991). Dynamic graciloplasty separates the gracilis tendon from its point of insertion at the knee, wraps the muscle around the anus, and attaches the tendon to the contralateral ischial tuberosity. To squeeze the anus closed, the gracilis muscle is then stimulated with an electrical pulse generator that is implanted in the abdominal wall. This procedure carries significant morbidity. It is not currently performed in the United States (Cera, 2005).

Implanting an artificial anal sphincter is another option, but again, it is infrequently performed in the United States. With this, a fluid-inflated cuff is implanted around the anus, a reservoir

balloon is placed within the abdominal wall, and a control pump is inserted into one labium majus. When fully inflated, the cuff occludes the anal canal. When defecation is desired, the control pump in the labia is squeezed to move fluid from the anal cuff into the reservoir balloon. The cuff, when fluid-empty, relaxes pressure around the anus and permits defecation. The fluid within the reservoir then returns to the anal cuff to restore pressure and continence (Christiansen, 1987).

ANORECTAL DISORDERS

Of functional gastrointestinal disorders, three *anorectal disorders* are described by the Rome IV Foundation expert consensus organization. These are FI, functional anorectal pain, and functional defecation disorders (Table 25-6). Anorectal disorders are defined by specific symptoms and, in the case of functional defecation disorders, also with abnormal diagnostic test results (Rao, 2016). A minimum duration of symptoms is required for diagnosis, and this avoids inclusion of self-limited conditions. Also, anorectal symptoms secondary to a neurologic or systemic disorder are not included in functional gastrointestinal disorders.

Fecal Incontinence

In Rome IV criteria, FI is defined as recurrent uncontrolled passage of fecal material for at least 3 months in an individual with a developmental age of at least 4 years. Stool that leaks at least two times in a 4-week period serves as a qualifying definition for research purposes. Recognized etiologies of FI, diagnostic testing, and treatment mirror those outlined earlier (p. 561).

Functional Anorectal Pain

Proctalgia fugax, *levator ani syndrome*, and *unspecified functional anorectal pain* are the three types of functional anorectal pain disorders described by Rome IV criteria. These present with chronic pain and are described fully in Chapter 12 (p. 270). The term *chronic proctalgia* is excluded from the new classification.

Functional Defecation Disorders

Within the *functional defecation disorders (FDD)* category, two subtypes are *inadequate defecatory propulsion* and *dyssynergic defecation* (see Table 25-6). Symptoms of excessive straining, feeling of incomplete evacuation, and digital facilitation of bowel movements are common in affected individuals. However, these symptoms do not consistently distinguish patients with FDDs from those without. Thus, FDD diagnosis relies also on physiologic testing, and impaired evacuation must be demonstrated in two of three tests. These are the balloon expulsion test, rectal evacuation imaging (defecography), and anorectal manometry or anal surface EMG. For FDD diagnosis, the Rome IV criteria also specify that a patient must satisfy diagnostic criteria for *functional constipation* and/or for *irritable bowel syndrome with predominant constipation*. The above criteria must be fulfilled for the last 3 months, with symptom onset at least 6 months before diagnosis.

TABLE 25-6. Rome IV Categories of Anorectal Disorders

Fecal incontinence
Functional anorectal pain
Functional defecation disorder
Inadequate defecatory propulsion
Dyssynergic defecation

For inadequate defecatory propulsion, diagnostic criteria include insufficient propulsive forces as measured by anorectal manometry. Poor propulsion may be with or without inappropriate contraction of the anal sphincter and/or pelvic floor muscles.

Dyssynergic defecation is characterized by failed relaxation of the puborectalis muscle and EAS. This disorder is common and is thought to account for 25 to 50 percent of chronic constipation cases (Bharucha, 2014; Wald, 1990). For dyssynergic defecation, women demonstrate adequate propulsive forces during attempted defecation but display inappropriate pelvic floor muscle contraction during anal surface EMG, anorectal manometry, and defecography. Other causes of constipation should be excluded. The utility of high-resolution manometry for identifying dyssynergic defecation is unclear (Grossi, 2016; Carrington, 2018). Because a considerable proportion of healthy people exhibit dyssynergia when tested with HRM, abnormal findings with two of the three tests mentioned earlier are required to confirm FDD.

The treatment of constipation is challenging and often ineffective. Schiller and associates (1984) showed that only 53 percent of patients were satisfied with traditional medical therapies. Biofeedback interventions for dyssynergic defecation teach patients to relax their pelvic floor and anal sphincter muscles while simultaneously raising intraabdominal and intrarectal pressures (Valsalva maneuver). The efficacy of biofeedback compared with laxatives in treating dyssynergic defecation was demonstrated in a controlled trial by Chiarioni and coworkers (2006). Moreover, biofeedback benefits were sustained at 1-year follow-up. In a randomized trial by Rao and colleagues (2007), biofeedback efficacy was compared with sham feedback therapy and with standard therapy (diet, exercise, laxatives) in 77 subjects with chronic constipation and dyssynergic defecation. Subjects in the biofeedback group had an increased number of complete spontaneous bowel movements, greater bowel function satisfaction, and a lower rate of digital evacuation maneuvers than subjects receiving standard or sham therapy. In addition, colonic transit time significantly improved in biofeedback and standard therapy subjects but not in subjects who received sham feedback. This suggests that colonic transit slowing is due to dyssynergia. Based on current data, biofeedback therapy is preferred for patients with dyssynergic defecation and chronic constipation, especially for those who have failed diet, exercise, and/or laxative therapy. The effectiveness of biofeedback for inadequate defecatory propulsion is currently unknown.

SNS does not improve bowel symptoms or rectal evacuation for FDDs (Bharucha, 2017). However, for patients with intractable constipation from other diagnoses, SNS is a promising therapeutic option (p. 567). Although not yet FDA approved

TABLE 25-7. Rectovaginal Fistula Risk Factors

Obstetric complications
Third- or fourth-degree laceration repair dehiscence
Unrecognized vaginal laceration during operative vaginal or precipitous delivery
Inflammatory bowel disease
Most commonly Crohn disease
Ulcerative colitis less common, as it is not a transmural disease
Infection
Most commonly cryptoglandular abscess located in the anterior aspect of the anal canal
Lymphogranuloma venereum
Tuberculosis
Bartholin gland duct abscess
Human immunodeficiency virus infection
Diverticular disease
Previous surgery in the anorectal area
Hemorrhoidectomy
Low anterior resection
Excision of rectal tumors
Hysterectomy
Posterior vaginal wall repairs
Pelvic radiation therapy
Neoplasm
Invasive cervical or vaginal cancer
Anal or rectal cancer
Trauma
Intraoperative
Coital

for this indication, a prospective study showed that SNS improved idiopathic slow- and normal-transit constipation that was refractory to conservative measures (Kamm, 2010). In this study, primary end points were greater defecation frequency, less straining, and decreased sensation of incomplete evacuation. Of 62 patients who underwent temporary generator placement, 73 percent proceeded to permanent generator implantation. Of these patients, 87 percent achieved treatment success.

RECTOVAGINAL FISTULA

Definition and Classification

Rectovaginal fistulas (RVFs) are congenital or acquired epithelium-lined tracts between the vagina and rectum. They are classified according to their location, size, and etiology. These features aid appropriate management and help predict surgical repair outcome. The underlying cause of a fistula is the most important predictor of outcome success, as it factors tissue robustness and overall patient health (Table 25-7).

Most RVFs are related to obstetric events and develop in the distal third of the vagina just above the hymen (Fig. 25-8) (Greenwald, 1978; Lowry, 1988; Tsang, 1998). Defect diameters range from <1 mm to several centimeters, and most communicate with the rectum at or above the pectinate (dentate) line (Fig. 38-21, p. 810). In contrast, fistulas with an opening below the dentate line are also appropriately called *anovaginal fistulas*. Surgical management of these "low" RVFs depends on the condition of the EAS but a perineal (transvaginal or transanal) approach is typical. Midlevel RVFs are found in the middle third of the vagina. High RVFs have their vaginal communication close to the cervix or the vaginal cuff. In cases with high RVFs, fistulas may open into the sigmoid colon and may not be readily seen on examination. They often require contrast or endoscopic studies for diagnosis. An abdominal approach is usually needed for repair. Last, fistula-in-ano is a tract that connects the perineal skin to the anal canal. It usually involves the anal sphincter muscles and often is considered a complex fistula.

Diagnosis

Patients with RVF usually complain of flatus or stool leakage per vagina. They may also present with recurrent bladder or vaginal

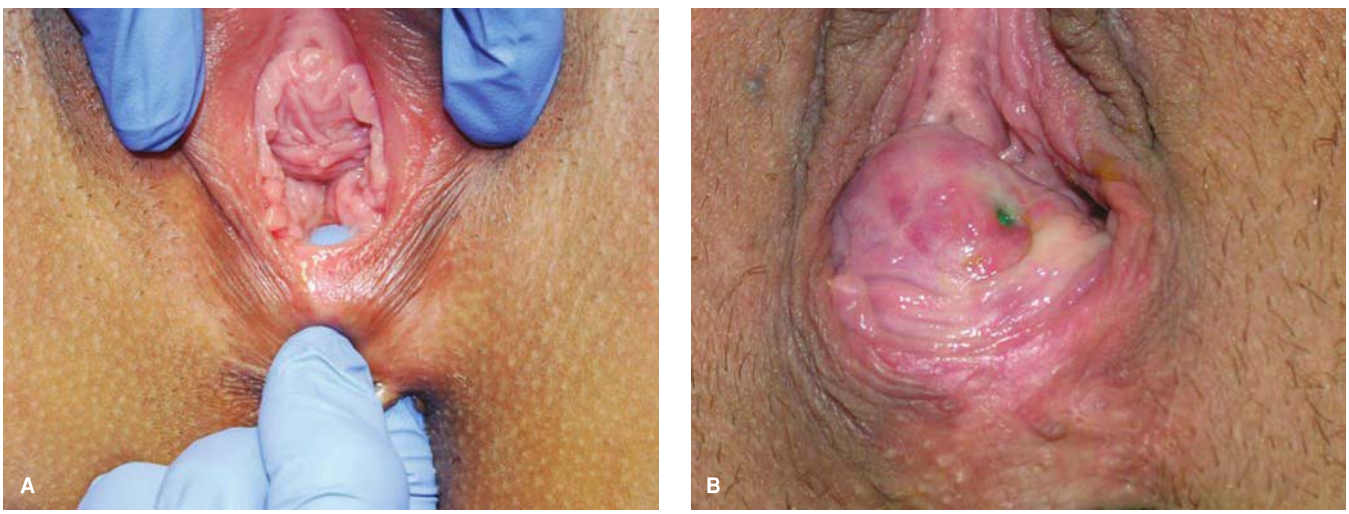

FIGURE 25-8 A. Gloved finger demonstrates rectovaginal fistula in the distal posterior vagina wall (Reproduced with permission of Dr. Meadow Good). **B.** The green glove of the examiner is seen through this smaller defect.

infection, rectal or vaginal bleeding, and pain. Symptoms often suggest the underlying etiology. For example, patients with obstetric injury and large defects of the anterior portion of the anal sphincters may have gross fecal incontinence. In contrast, those with an infectious or inflammatory process may complain of diarrhea, abdominal cramping, and fevers in addition to vaginal passage of stool.

During physical examination, most low RVFs can be visualized during inspection of the perineum and distal portion of the posterior vaginal wall. Rectovaginal examination assesses the thickness of the perineal body and anovaginal wall and may allow palpation and visualization of the defect. Some RVFs that are not readily seen on initial examination can be identified by noting air bubbles at the fistula's vaginal opening after filling the vagina with water during vaginoscopy (Chap. 44, p. 1055). Alternatively, methylene blue can be instilled in the rectum after a tampon is placed in the vagina. The fistula and a gross assessment of its location can be identified by inspecting the level of blue staining on the tampon following its removal.

If the fistula site is not determined by the preceding maneuvers, a contrast study is indicated. These include barium enema or computed tomography (CT) scanning that includes oral contrast.

Unless RVFs are obviously due to a prior obstetric event, a biopsy of the fistulous tract is indicated to investigate possible malignancy or inflammatory conditions. In addition, proctoscopy or colonoscopy is often warranted if inflammatory bowel disease, malignancy, or gastrointestinal infection is suspected. Anal sphincter function assessment is essential, as function plays an integral role in repair selection.

Treatment

Treatment of RVF depends on the underlying etiology and the defect's size and location. Some women with small RVFs following recent obstetric trauma may be followed conservatively in anticipation of spontaneous healing (Goldaber, 1993; Rahman, 2003). For small RVFs without inflammation, some data also support repair within 72 hours of trauma (Malik, 2008). If surgical repair is required, it is delayed until surrounding tissues are free of edema, induration, and infection (Wiskind, 1992). As an aid and temporizing measure, a draining seton (suture or vessel loop) can be passed through a fistulous tract to allow fistula maturation prior to more definitive repair (Rogers, 2016; Vogel, 2016).

Larger obstetric-related defects and other low RVFs are most often corrected surgically. Surgical techniques for low RVFs include a fistulotomy (surgical opening of a fistulous tract) and then transvaginal purse-string repair. Instead, a fistulectomy plus a tension-free layered closure is common and illustrated in Chapter 45 (p. 1153). Last, a transperineal approach through an episioproctotomy converts the defect into a complete perineal tear, that is, a fourth-degree laceration, which then is reconstructed. This approach only should be considered for RVFs in women with extensive anal sphincter defects and associated fecal incontinence. A promising approach for simple and complex anal fistulas is the ligation of the intersphincteric fistula tract (LIFT) procedure (Alasari, 2014). It involves suture closure and division of the fistula tract in the intersphincteric plane. The LIFT procedure results in fistula healing in 61 to 94 percent of patients, with little morbidity and rare alterations in fecal continence (Vogel, 2016). Last, endorectal flap advancement, with or without sphincteroplasty, is a common procedure used by colorectal surgeons (MacRae, 1995; Vogel, 2016). With flap advancement, the fistulous tract is excised, a broad-based flap of rectal wall is employed to obliterate the fistula's origin, and sphincter muscle division is avoided. In patients with RVF complicated by fecal incontinence, RVF repair and anal sphincteroplasties in general provide better outcomes compared with endorectal advancement flap alone (Tsang, 1998). Thus, in patients with low RVFs, preoperative endoanal sonography of the anal sphincters is important. Namely, an episioproctotomy is avoided if the external anal sphincter is intact to reduce fecal incontinence rates (Hull, 2007).

Midlevel vaginal fistulas also are often due to obstetric trauma and are repaired transvaginally or transanally by a tension-free layered closure or an endorectal advancement flap. High fistulas are most commonly repaired by a transabdominal approach using bowel resection of the involved segment followed by primary bowel reanastomosis. An omental J flap or epiploic appendages of the colon can be used for tissue interposition during abdominal approaches.

Success rates vary depending on the underlying cause and repair method. Successful repair rates following obstetric injury vary from 78 to 100 percent (Khanduja, 1999; Tsang, 1998). Rates of 40 to 50 percent are reported with the rectal advancement flaps, and rates are more than 70 percent with episioproctotomy (Hull, 2007; Mizrahi, 2002; Sonoda, 2002). Fistulas due to other etiologies such as radiation, cancer, or active inflammatory bowel disease are more difficult to treat successfully. A labial fat interposition graft (modified Martius flap) may be considered in these cases to enhance blood supply and tissue healing. A gracilis muscle flap is another option, but data are limited. In general, success rates are highest with the first surgical attempt at repair (Lowry, 1988).).

GENITOURINARY FISTULA

A genitourinary fistula is defined as an abnormal communication between the urinary (ureters, bladder, urethra) and the genital (uterus, cervix, vagina) systems. The true incidence is unknown and varies according to whether the etiology is obstetric or gynecologic. In Asia and Africa, up to 100,000 new cases of obstetric genitourinary fistula are added each year to the estimated pool of 2 million women with unrepaired fistulas (World Health Organization, 2018). For industrialized countries, most fistulas occur iatrogenically from pelvic surgery, and the generally accepted incidence derives from data on surgeries to correct these fistulas. Numbers from the National Hospital Discharge Survey of inpatient women show that approximately 5 per 100,000 women underwent lower reproductive tract fistula repair (Brown, 2012). This likely is underestimated, as many cases are unreported, unrecognized, or treated conservatively. Of genitourinary fistulas, vesicovaginal fistula is most common (Goodwin, 1980; Shaw, 2014).

PATHOPHYSIOLOGY

The principles and phases of wound healing aid the understanding of genitourinary fistula pathogenesis. After injury, tissue damage and necrosis stimulate inflammation, and the process of cell regeneration begins (Kumar, 2015). Initially at the injury site, new blood vessels form, that is, a*ngiogenesis*. Three to 5 days after injury, fibroblasts proliferate and subsequently synthesize and deposit extracellular matrix, in particular collagen. This *fibrosis phase* determines the final strength of the healed wound. Collagen deposition peaks approximately 7 days after injury and continues for several weeks. Subsequent scar maturation and organization, termed *remodeling*, augments wound strength. These phases are interdependent, and any disruption of this sequence eventually may create a fistula. Most defects tend to present 1 to 3 weeks after tissue injury. This is a time during which tissues are most vulnerable to an altered healing environment that may include hypoxia, ischemia, malnutrition, radiation, and chemotherapy. Eventually, edges of the wound epithelialize, and a chronic fistulous tract is thus formed.

CLASSIFICATION

Although many classification systems exist for genitourinary fistula, no single system is considered the accepted standard nor is any one scheme superior in predicting surgical success. Fistulas can develop at any point between the genital and urinary systems, and one classification method reflects the anatomic communication (Table 26-1).

TABLE 26-1. Classification of Genitourinary Fistula Based on Anatomic Communication

	Urinary Tract		
	Ureter	**Bladder**	**Urethra**
Vagina	Ureterovaginal	Vesicovaginal	Urethrovaginal
	Vesicoureterovaginal		
Cervix	Ureterocervical	Vesicocervical	Urethrocervical
Uterus	Ureterouterine	Vesicouterine	Not reported

TABLE 26-2. Classification of Vesicovaginal Fistulas

Simple
Size <2 to 3 cm
Located near the cuff (supratrigonal)
No prior radiation or malignancy
Normal vaginal length
Complicated
Prior radiation therapy
Pelvic malignancy present
Vaginal length shortened
Size >3 cm
Located distant from cuff or has trigonal involvement

Vesicovaginal fistulas can also be characterized by their size and location in the vagina. They are termed *high vaginal*, when found proximally in the vagina; *low vaginal*, when noted distally; or *midvaginal*, when identified centrally. For instance, posthysterectomy vesicovaginal fistulas are often proximal, or "high" in the vagina, and located at the level of the vaginal cuff.

Others classify vesicovaginal fistula based on the complexity and extent of involvement (Table 26-2) (Elkins, 1999). In this scheme, complicated vesicovaginal fistulas are those that involve pelvic malignancy, prior radiation therapy, a shortened vaginal length, or bladder trigone; those that are distant from the vaginal cuff; or those that measure >3 cm in diameter.

In one obstetric classification system, high-risk vesicovaginal fistulas are described by their size (>4 to 5 cm in diameter); involvement of urethra, ureter(s), or rectum; juxtacervical location with an inability to visualize the superior edge; and reformation following a failed repair (Elkins, 1999).

Another obstetric classification ranks urinary fistulas based on their needed surgical repairs (Waaldijk, 1995). In this system, type I fistulas are those that do not involve the urethral closure mechanism, type II fistulas do, and type III fistulas involve the ureter and include other exceptional fistulas. Type II fistulas are divided into: (A) without or (B) with subtotal or total urethra involvement. Type IIB fistulas are further subdivided as: (a) without or (b) with a circumferential configuration around the urethra.

To aid objective comparison of surgical outcomes, a more comprehensive classification system has been developed (Table 26-3). It integrates fistula distance from the external urethral meatus, fistula size, degree of surrounding tissue fibrosis, and extent of vaginal length reduction (Goh, 2004). This system has good inter- and intraobserver reproducibility and has demonstrated efficacy in predicting which patients are at risk of postfistula urinary incontinence and of failed closure (Bengtson, 2016; Goh, 2008, 2009). Despite the availability of these numerous classification systems, most clinicians will, from a practical standpoint, often describe the communicating structures and the defect's relative position in the vagina (high, mid, low).

TABLE 26-3. Classification of Genitourinary Fistulas

This new classification divides genitourinary fistulas into four main types, depending on the distance of the fistula's distal edge from the external urinary meatus. These four types are further subclassified by the size of the fistula, extent of associated scarring, vaginal length, or special considerations.
Type 1: Distal edge of fistula >3.5 cm from external urinary meatus
Type 2: Distal edge of fistula >2.5–3.5 cm from external urinary meatus
Type 3: Distal edge of fistula 1.5 to >2.5 cm from external urinary meatus
Type 4: Distal edge of fistula <1.5 cm from external urinary meatus
(a) Size <1.5 cm, in the largest diameter
(b) Size 1.5–3 cm, in the largest diameter
(c) Size >3 cm, in the largest diameter
i. None or only mild fibrosis (around fistula and/or vagina) and/or vaginal length >6 cm, normal capacity
ii. Moderate or severe fibrosis (around fistula and/or vagina) and/or reduced vaginal length and/or capacity
iii. Special consideration, e.g., postradiation, ureteric involvement, circumferential fistula, or previous repair

Data from Goh, 2004, with permission.

ETIOLOGY

Congenital genitourinary fistulas are rare. If found, they are commonly associated with other renal or urogenital abnormalities. Thus, most vesicovaginal fistulas are acquired and typically result from either obstetric trauma or pelvic surgery.

Obstetric Trauma

In developing countries, more than 70 percent of genitourinary fistulas arise from obstetric trauma, specifically from prolonged or obstructed labor or complicated cesarean delivery (Kumar, 2009; Raassen, 2014). Often, their development reflects social or regional obstetric practices. For example, both childbearing at a young age, before the pelvis has completely developed, and female genital mutilation may significantly narrow the vaginal introitus and obstruct labor. Prolonged obstructed labor or malpresentation of the presenting fetal part can cause pressure or ischemic necrosis of the anterior vaginal wall and bladder, subsequently resulting in fistula formation. Symphysiotomy to relieve obstructed labor also carries fistula risk (Wilson, 2016). The vagina may also be damaged by instruments used to deliver stillborn neonates or to perform abortion. Malnutrition and limited health care in many of these countries can further diminish wound healing.

In contrast, in most developed countries, fistulas uncommonly follow obstetric procedures or deliveries. Rarely, cesarean deliveries, usually those accompanied by obstetric complications, have led to complex urinary fistula (Billmeyer, 2001). Similarly, rare cases following cervical cerclage have been reported (Massengill, 2012).

Pelvic Surgery

In developed countries, iatrogenic injury during pelvic surgery is responsible for 90 percent of vesicovaginal fistulas, and the

accepted incidence of fistula formation after pelvic surgery is 0.1 to 2 percent (Hilton, 2012a,b; Tancer, 1992). The remaining fistulas result from procedures performed by urologists and by colorectal, vascular, and general surgeons. In industrialized countries, hysterectomy is the most common surgical precursor to vesicovaginal fistula, accounting for approximately 75 percent of fistula cases (Symmonds, 1984). When all hysterectomy types are considered, vesicovaginal fistula is estimated to complicate 0.8 per 1000 procedures (Harkki-Siren, 1998). In their review of more than 62,000 hysterectomy cases, laparoscopic hysterectomies were associated with the greatest incidence (2 per 1000), followed by abdominal (1 per 1000), vaginal (0.2 per 1000), and supracervical (0 per 1000) hysterectomies. With hysterectomy for benign disease, bladder wall laceration extending into the bladder neck or ureteral orifice (trigone) significantly raised the risk of subsequent vesicovaginal fistula (Duong, 2009).

Because most genitourinary fistulas follow pelvic surgery, prevention and intraoperative recognition of lower urinary tract injury is imperative. Discussed in Chapter 40 (p. 867), intraoperative cystoscopy improves the detection rate of lower urinary tract injuries. In one study of nearly 3000 benign hysterectomies, rates of vesicovaginal fistula dropped significantly after universal cystoscopy was implemented (Chi, 2016). Thus, intraoperative cystoscopy can be a useful adjunct, particularly in cases posing greater risk for ureteral or bladder injury.

Other Causes

Although surgical and obstetric causes account for most urinary fistulas, other etiologies include radiation therapy, malignancy, trauma, foreign bodies, infections, pelvic inflammation, and inflammatory bowel disease.

Radiation therapy induces an endarteritis that can lead to tissue necrosis and subsequent fistula formation. This modality is a frequent cause, and some series have reported that up to 6 percent of genitourinary fistulas can result from radiation (Lee, 1988). Although most damage following this therapy develops within weeks and months, associated fistulas may present up to 20 years after the original insult (Graham, 1967; Zoubek, 1989).

Malignancy is commonly linked with tissue necrosis and may lead to genitourinary fistula. Emmert and Kohler (1996) found a 1.8-percent incidence of rectovaginal and vesicovaginal fistula in their analysis of nearly 2100 women with cervical cancer. Thus, tissue biopsy is routinely considered during diagnostic evaluation of women with a fistula and history of malignancy.

Trauma sustained during sexual activity or sexual assault can result in genitourinary fistula and has been estimated to precede 4 percent of these defects (Kallol, 2002; Lee, 1988). Foreign bodies such as a neglected pessary or vesical calculi also are documented causes (Arias, 2008; Shephard, 2017). Given that transurethral catheter placement has been linked to urethrovaginal fistula, this commonly used device should be placed, maintained, and removed with care (Dakhil, 2014). Foreign material introduced during surgery such as collagen injected transurethrally and complications resulting from synthetic mesh placement for urinary incontinence or pelvic organ prolapse are other inciting agents (Blavais, 2014; Firoozi, 2012; Pruthi, 2000). Also, during sling surgeries, excess sling tension may increase tissue stress and necrosis. Thus, initial material selection and patient evaluation for poor wound healing risk factors are important prevention steps (Giles, 2005). Mesh selection is further discussed in Chapter 24 (p. 554).

Other rare causes of fistula formation include infections such as lymphogranuloma venereum, urinary tuberculosis, pelvic inflammation, and syphilis; inflammatory bowel disease; and autoimmune disease (Ba-Thike, 1992; Monteiro, 1995). Additionally, poor wound healing is often linked to poorly controlled diabetes mellitus, smoking, peripheral vascular disease, and chronic corticosteroid therapy.

SYMPTOMS

Vesicovaginal fistula classically presents with unexplained continuous urinary leakage from the vagina after a recent operation. Depending on the size and location of the fistula, the urine amount will vary. Occasionally, small-volume, intermittent leakage is mistaken for postoperative stress urinary incontinence or a normal exudate associated with cuff healing. Thus, new-onset urinary or vaginal leakage, particularly in the setting of recent pelvic surgery, ideally prompts thorough examination to exclude fistula. Other less specific symptoms of genitourinary fistula include fever, pain, ileus, and bladder irritability.

Vesicovaginal fistula may present days to weeks after the inciting surgery, and those following hysterectomy typically present at 1 to 3 weeks. Some fistulas, however, have longer latency, and symptoms may develop several years later.

DIAGNOSIS

A thorough history and physical examination identifies most cases of vesicovaginal fistula. Accordingly, information is documented regarding obstetric deliveries, prior surgeries, previous fistula management, and malignancy treatment, especially pelvic surgery and radiation therapy.

Physical examination is equally informative, and vaginal inspection often will identify the defect (Fig. 26-1). A meticulous assessment for other fistulous tracts is performed, and their location and size are noted. Visual assistance with an endoscopic lens and translucent vaginal speculum can sometimes help identify a vaginal-apex fistula, which can be more difficult to detect.

It is essential to differentiate between "extraurethral" urinary leakage, as with a fistula, and "transurethral" leakage, that is, through the urethra, as with stress urinary incontinence. Occasionally, the vaginal fluid source is unclear, and a small amount of urine can easily be mistaken for vaginal discharge. Measurement of the vaginal fluid's creatinine content can sometimes be used to confirm its origin. Although creatinine levels in urine vary, with mean levels reaching 113.5 mg/dL, a value >17 mg/dL is consistent with urine (Barr, 2005). In contrast, fluid with a concentration <5 mg/dL is highly unlikely to be human urine.

Although a genitourinary fistula ideally is visualized directly, inspection at times is unrevealing. In these circumstances,

FIGURE 26-1 In this image, the anterior vaginal wall is elevated by open ring forceps. The urethra is seen between the forceps arms, and urine streams from a vesicovaginal fistula.

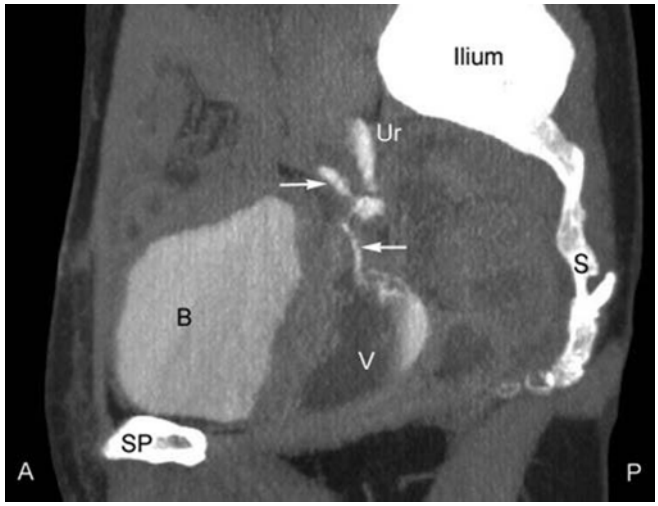

FIGURE 26-3 Ureterovaginal fistula. Both arrows show anomalous tracking of contrast. The lower arrow denotes a fistulous tract to the upper vagina. B = bladder; S = sacrum; SP = symphysis pubis; Ur = ureter; V = vagina. (Reproduced with permission from Dr. April Bailey.)

retrograde bladder instillation of visually distinct solutions such as sterile milk or dilute methylene blue can often indicate a fistula and aid in its localization.

If the presence of a urinary fistula is uncertain or its vaginal location is not identified, a *three-swab test*, commonly known as the "tampon test," is recommended (Moir, 1973). Although some literally use a tampon to perform this test, we recommend using two to four pieces of gauze sequentially packed into the vaginal canal. A diluted solution of methylene blue is instilled into the bladder using a transurethral catheter. After 15 to 30 minutes of routine activity, the gauze is removed serially from the vagina, and each is inspected for dye. The specific gauze colored with dye suggests the fistula location—a proximal or high location in the vagina for the innermost gauze and a low or distal fistula for the outermost. If the distally placed sponge is stained with dye, urine leaking out through the urethra, as with stress urinary incontinence, must be differentiated from fistula drainage.

Cystourethroscopy is another valuable diagnostic tool (Fig. 26-2). It permits fistula localization, determination of its proximity to the ureteral orifices, inspection for multiple fistula sites, and assessment of surrounding bladder mucosa viability. In addition, cystourethroscopy and vaginoscopy used sequentially at the same visit has been described to identify vesicovaginal fistula (Andreoni, 2003).

Concomitant ureteral involvement is estimated to complicate 10 to 15 percent of vesicovaginal fistula cases and is sought during diagnostic evaluation (Goodwin, 1980). At our institution, intravenous contrast-enhanced computed tomography (CT) scanning in the excretory phase (CT urogram) is the preferred diagnostic test after initial cystourethroscopic survey is completed (Fig. 26-3). Selection of modalities other

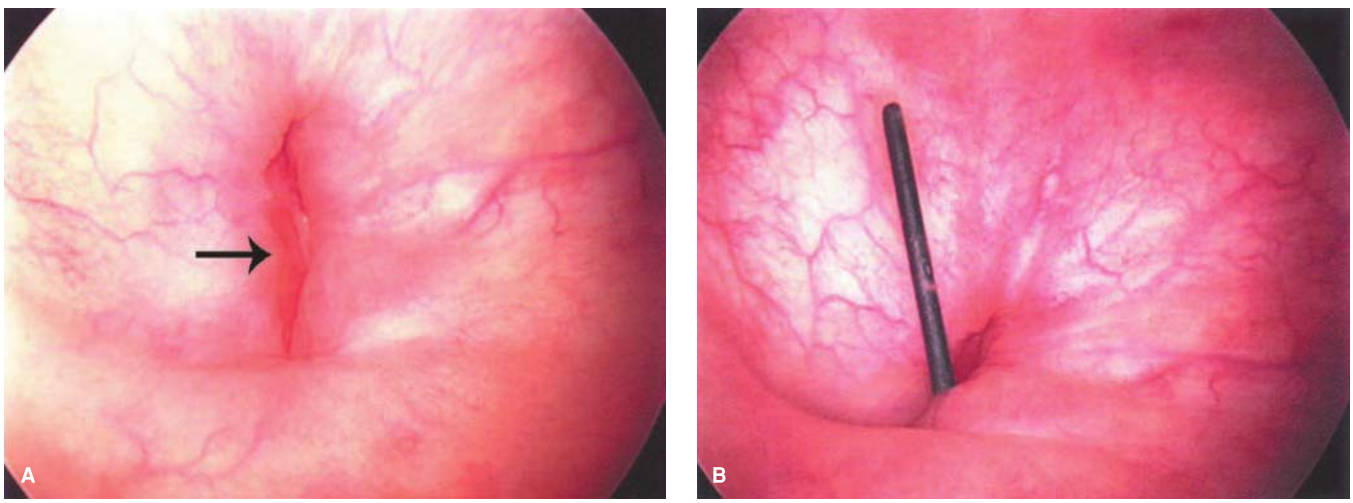

FIGURE 26-2 **A.** Cystoscopic view of vesicovaginal fistula (*arrow*). **B.** Probe placed through fistulous tract to aid cystoscopic visualization.

than CT for fistulous tract identification may be considered based on cost or availability. First, intravenous pyelography (IVP) can adequately confirm integrity of the upper collecting system and exclude ureteral involvement in a fistula. Second, retrograde pyelography may be used. Often carried out in conjunction with cystoscopy, it is performed by placing a small catheter into the distal ureter. Contrast material is injected through the catheter into one or both ureters. Fluoroscopic images are then obtained. Retrograde pyelography generally has been reported to have the same diagnostic value as IVP.

In some instances resources are scarce, cost may be a limitation, and access to specialized diagnostic imaging is a challenge. With some advanced planning, phenazopyridine hydrochloride (Pyridium) can be used in conjunction with the three-swab test to determine ureteral involvement, as a very rudimentary alternative to the aforementioned more sophisticated imaging. This tablet is administered orally, is excreted renally, acts as a topical bladder analgesic, and stains urine orange as a side effect. Women with suspected ureteral involvement are instructed to take a 200-mg dose a few hours before their clinic appointment. The steps of the three-swab test are then performed, as described earlier (p. 577). In this case, if the most proximal (innermost) gauze is colored with orange dye, ureteral involvement is suspected. If both orange and blue dyes are seen, then involvement of both the bladder and ureter(s) is suspected.

Voiding cystourethrography (VCUG) can help confirm the presence, location, and number of fistulous tracts. In this, the bladder is filled via catheter with contrast dye. Fluoroscopic images of the lower urinary tract are then obtained during patient micturition. However, CT has largely replaced this modality. Transabdominal sonography with applied color Doppler to identify flow through the fistula has been suggested as another diagnostic option (Volkmer, 2000). However, without color Doppler, sonography failed to identify 29 percent of vesicovaginal fistula cases in one study (Adetiloye, 2000).

TREATMENT

Conservative Treatment

Occasionally, genitourinary fistulas may spontaneously close during continuous bladder drainage using an indwelling urinary catheter. Approximately 12 percent of women treated by sustained catheterization alone had fistulas that healed spontaneously (Oakley, 2014; Waaldijk, 1994). Romics and colleagues (2002) found that in 10 percent of cases, urinary fistulas close spontaneously after 2 to 8 weeks of transurethral catheterization, especially if the fistula is small (2- to 3-mm diameter). Another series reported fistulas up to 2 cm in diameter spontaneously healed in 50 to 60 percent of patients treated with an indwelling catheter (Waaldijk, 1989).

Despite these series, data that correlate fistula size and success of conservative management are limited. Many reports of successful spontaneous closure with catheter drainage have been limited to fistulas that were 1 cm in size or smaller (Lentz, 2005; Ou, 2004). Many studies are vague regarding how fistula size is measured, and each series has potential for considerable bias in its selection criteria. However, in general, the larger a fistula, the less likely it is to heal without surgery.

Evidence regarding the duration of catheter drainage also varies. Regardless, many agree that if a fistula has not closed within 4 weeks, it is unlikely to do so. This may be secondary to epithelialization of the fistulous tract (Davits, 1991; Tancer, 1992). Moreover, continued urinary drainage may lead to further bladder inflammation and irritation (Zimmern, 1991). Importantly, if attempting conservative treatment of a vesicovaginal fistula with catheter insertion and chronic drainage, urinary drainage ideally begins shortly after the inciting event.

Fibrin sealant (Tisseel, Evicel), also colloquially called *fibrin glue*, is formed from concentrated fibrinogen combined with thrombin to simulate the final clotting cascade stages. In gynecology, it is mainly used to control low-pressure surgical bleeding. Although fibrin sealant has been described for vesicovaginal fistula treatment, it is often selected as a surgical adjunct rather than primary surgical treatment (Evans, 2003). Data regarding fibrin sealant effectiveness are sparse, and well-designed trials are lacking. Thus, fibrin sealant monotherapy may not be the initial recommended treatment in most vesicovaginal fistula cases due to potential lack of durability and thus a risk for recurrence. However, it may provide a viable alternative in patients with multiple comorbidities that contraindicate a prolonged fistula repair surgery.

In sum, a trial of conservative therapy is usually warranted and reasonable, especially if instituted shortly after the inciting event and if the fistula is small. However, gains from a conservative approach are balanced against a patient's desire for an expedited repair to resolve the leak. Thus, the timing of intervention ideally achieves a compromise between reasonable conservative efforts and addressing the patient's immediate distress and quality of life. As noted, most urinary fistulas ultimately require surgical intervention.

Surgical Treatment

Incorporating the fundamentals of genitourinary fistula repair is essential to successful resolution. These include accurate fistula delineation; adequate assessment of surrounding tissue vascularity; timely repair; multilayer, tension-free, and watertight defect closure; and postoperative bladder drainage.

Primary surgical repair of genitourinary fistula is associated with high cure rates (75 to 100 percent) (Rovner, 2012b). Factors that support this rate include adequate vascularity of the surrounding tissue, brief fistulous tract duration, no prior radiation therapy, meticulous surgical technique, and surgeon experience. The first attempt at surgical repair is usually associated with the best chance of successful healing. Surgical repair success rates specifically for obstetric fistulas also are high. Of these, 81 percent are corrected with the first attempt, and 65 percent with the second (Elkins, 1994; Hilton, 1998).

Timing of Repair

One principle of fistula repair dictates that a repair be performed in noninfected and noninflamed tissues. Early surgical intervention of uncomplicated fistulas within the first 24 to 48 hours following the inciting surgery is possible, as it avoids

the brisk postoperative inflammatory response. Such early closure does not affect success rates, and it appears to reduce social and psychologic patient distress (Blaivas, 1995; Persky, 1979).

In instances of extensive and severe inflammation, we recommend delaying operative repair for 6 weeks until inflammation subsides. During this time, a trial of catheter drainage, while the surrounding tissue has an opportunity to heal, is reasonable.

Route of Surgical Repair

Different surgical repair options are available for vesicovaginal fistula. However, data that support an optimal route are limited, and the lack of consensus may reflect variances in surgeon experience and preference. Among important surgical considerations, ability to gain access to the fistula is essential and commonly dictates the approach. Fortunately, success rates are high whether the route of repair is transvaginal or transabdominal.

Vaginal. The transvaginal approach to genitourinary fistula repair is straightforward and direct. Compared with abdominal approaches, it is associated with shorter operative times, decreased blood loss, less morbidity, and shorter hospital stays (Wang, 1990). The transvaginal route also allows easy access for ancillary equipment, such as ureteral stents. This is particularly useful if the fistula is located near ureteral orifices.

One transvaginal approach used most commonly by gynecologists, the *Latzko technique*, is illustrated in Chapter 45 (p. 1081). In this technique, likened to a partial colpocleisis, the most proximal portions of the anterior and posterior vaginal walls are surgically apposed to close the defect, without completely removing the fistulous tract. This partially obliterates the upper vagina, similar to that achieved by colpocleisis. Because of the potential for vaginal shortening, this technique may not be appropriate if vaginal depth has already been compromised or if sexual dysfunction preexists. If use of the Latzko technique is anticipated, patient counseling should specifically addresses these issues and potential sequelae. That said, recent studies evaluating sexual function show similar or higher functioning scores following vaginal repair routes compared with abdominal routes (Lee, 2014; Mohr, 2014).

The *classical technique*, in contrast to the Latzko method, involves total excision of the fistulous tract and mobilization of the surrounding anterior vaginal wall epithelium. After tract resection, the bladder mucosa is first closed, and a watertight repair is confirmed. This is followed by closure of one or two layers of fibromuscular tissue. Vaginal epithelium is then reapproximated.

Of the two approaches, some favor incomplete fistulous tract excision (Latzko repair) to avoid weakening the surrounding tissue, enlarging the defect, and thereby potentially compromising the repair. By preserving the presumptively stronger scar tissue surrounding the fistula, it theoretically permits a more secure reapproximation of surrounding tissue.

Abdominal (Transperitoneal). With this route, the fistula is accessed and excised through an intentional cystotomy on the preperitoneal side of the bladder as shown in Chapter 45 (p. 1084). This approach is used for situations in which the fistula: (1) is located proximally in a narrow vagina, (2) lies close to the ureteral orifices, (3) is complicated by a concomitant ureteric fistula, (4) persists after prior repair attempts, (5) is large or complex in configuration, or (7) requires an abdominal interposition graft, described in the next section.

Evidence-based support for laparoscopic genitourinary fistula repair is limited to case series (Miklos, 2015). The technique requires advanced laparoscopic surgical skills. Accordingly, success with this approach appears to be highly dependent on surgeon experience.

Interposition Flaps. Surrounding tissue vascularity is essential for successful genitourinary fistula repair healing. When intervening tissues for fistula closure are thin and poorly vascularized, various tissue flaps may be placed vaginally or abdominally between the bladder and the vagina in an attempt to enhance the repair and to lend support and blood supply (Eisen, 1974; Martius, 1928). Sections 45-2 and 45-11 of the atlas illustrate the omental J-flap, which is an abdominal option, whereas a Martius bulbospongiosus fat pad flap is used during vaginal procedures (p. 1085). Although interposition flaps are useful in situations where tissue viability is in question, their utility in uncomplicated cases of vesicovaginal fistula is unclear.

Other Genitourinary Fistulas

Although vesicovaginal fistulas are the most common type of genitourinary fistula, other defects can develop and may be described based on their communication between anatomic structures (see Table 26-1). Urethrovaginal fistulas commonly result from surgery involving the anterior vaginal wall, in particular anterior colporrhaphy and urethral diverticulectomy (Blaivas, 1989; Scholler, 2018). In developing countries, as with vesicovaginal fistula, obstetric trauma remains the most common cause of urethrovaginal fistulas. Frequently, patients present with continuous urinary drainage into the vagina or with stress urinary incontinence. The principles of repair are similar, namely, layered closure, tension-free repair, and postoperative bladder drainage.

URETHRAL DIVERTICULUM

Along the anterior vaginal wall, paraurethral glands communicate directly with the urethra. A urethral diverticulum commonly forms from a cystic enlargement of one of these obstructed glands, which then bulges into the anterior vaginal wall. This may develop at the proximal, mid, or distal urethra. This outpouching is commonly asymptomatic but may require surgical excision for symptoms.

Urethral diverticulum is reported to develop in 1 to 6 percent of the general female population. With greater awareness and radiologic advances, diagnosis rates are increasing (Rovner, 2012a). In one population-based study, the incidence was estimated to be <0.02 percent (El-Nashar, 2014). However, the true incidence may be underestimated because diverticula are frequently asymptomatic and thus underreported. In women with lower urinary tract symptoms, the incidence dramatically rises and may reach 40 percent (Stewart, 1981).

Urethral diverticulum is diagnosed most often in the third to sixth decades of life and more commonly in females than in

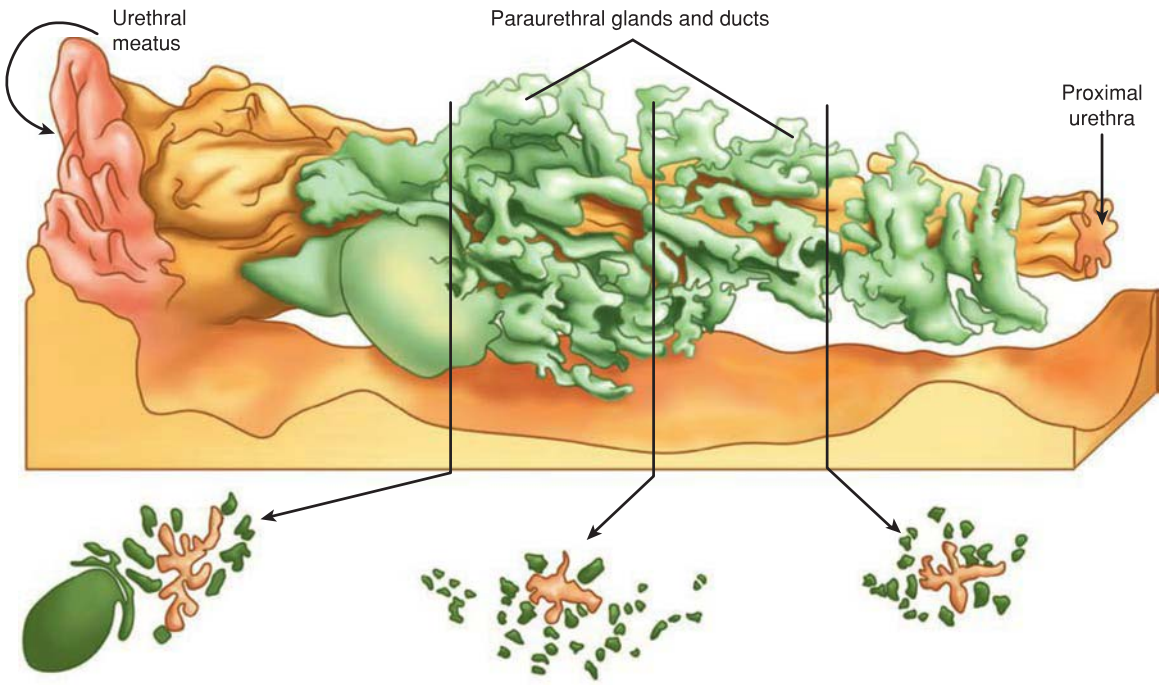

FIGURE 26-4 Complex configuration of paraurethral glands. Cross sections at the bottom show the variable gland distribution along the urethral length.

males (Aldridge, 1978; Burrows, 2005). In some studies, but not all, a greater predominance of urethral diverticula is noted in African-Americans compared with whites (Davis, 1970; Leach, 1987; Burrows, 2005).

ETIOLOGY

The cause of urethral diverticula is unclear. Most are acquired, but rare congenital diverticula have been reported. Congenital causes include persistence of embryologic remnants, defective closure of the ventral portion of the urethra, and congenital cystic dilation of paraurethral glands (Ratner, 1949). Embryology of the female genital tract, described in Chapter 19 (p. 406), contributes in part to our understanding of congenital urethral diverticulum. During female development, the müllerian ducts form the upper vagina, whereas the urogenital sinus gives rise to the distal vagina, vestibule, and female urethra (Fig. 19-4, p. 410). In the vagina, müllerian mucinous columnar epithelium is replaced by squamous epithelium of the urogenital sinus. When the process of epithelial replacement is arrested, small foci of müllerian epithelium may persist and form cysts or diverticula.

In contrast, acquired diverticula can result from infection, birth trauma, or traumatic instrumentation. The most widely held theory dates back to Routh (1890) and involves the paraurethral glands and their ducts. The paraurethral glands surround and cluster most densely along the urethra's inferolateral border (Fig. 26-4) (Huffman, 1948). Of these glands, the bilateral Skene glands are the most distal and typically the largest. Paraurethral glands connect to the urethral canal via a network of branching ducts. The arborizing pattern in portions of this network helps to explain the complexity of some urethral diverticula (Vakili, 2003).

Routh theorized that infection and inflammation obstruct individual ducts and lead to cystic dilation. If these do not spontaneously resolve or infection is not treated promptly, an abscess can form. Subsequent abscess expansion and continued inflammation may rupture the gland into the urethra. These rupture at any location along the mid to distal urethral lumen to create a fistula between the two (Fig. 26-5). As infection clears, the dilated diverticular sac and its new communicating ostium into the urethra persist. Of infectious agents, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are organisms that were once commonly associated with urethritis and severe inflammation of the paraurethral glands. However, positive identification of these organisms is no longer a prerequisite for diagnosis. More often than not, urethral cultures from women with diverticula are unrevealing.

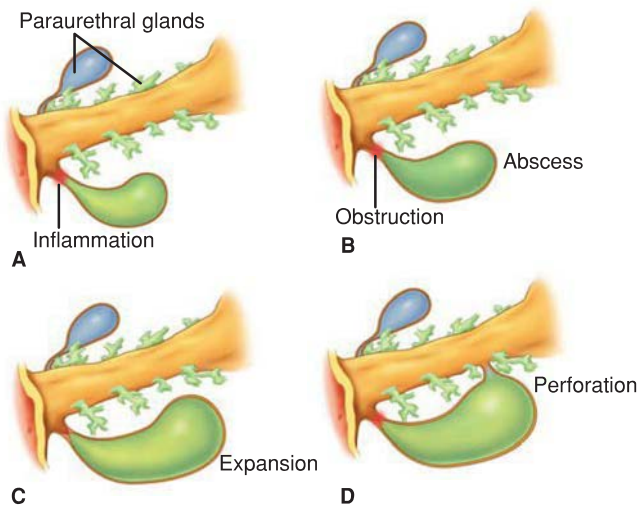

FIGURE 26-5 Mechanism of urethral diverticulum development.

In addition to infection, injured urethral tissue can swell and obstruct paraurethral ducts. Urethral trauma may stem from childbirth, urethral instrumentation, female genital mutilation, placement or removal of synthetic midurethral slings, or periurethral bulking agents (Athanasopoulos, 2008; Chan, 2015; Clemens, 2001; McNally, 1935).

CLASSIFICATION

Early classification systems organized urethral diverticula according to their radiographic complexity and described them as: (1) simple saccular, (2) multiple, or (3) compound or complex with branching sinuses (Lang, 1959). To help standardize surgical treatment and study efficacy, Ginsburg and Genadry (1983) created a preoperative classification system based on urethral location. This system organized diverticula based on their urethral location and described lesions as type 1 (proximal third), type 2 (middle third), and type 3 (distal third).

To achieve a similar end, Leach and coworkers (1993) constructed the L/N/S/C3 classification system. In this system, the diverticulum characteristics are described according to its location (L), number (N), size (S), and configuration, communication, and continence status of the patient (C3). Location describes lesions as being distal, mid-, or proximal urethral and as extending or not extending beneath the bladder neck. In Leach's series of 61 patients, most diverticula were midurethral. Logically, this distribution reflects the predominance of paraurethral glands along the middle third of the urethra. Ascertainment of the number of diverticula is important to prevent incomplete excision of multiple lesions and thus symptom persistence. Diverticulum size similarly can influence treatment. For example, some recommend concomitant interposition flaps for a large diverticulum. Moreover, urinary incontinence may develop de novo or persist if the diverticulum is extremely large and involves sphincter continence mechanisms.

Diverticula variably wrap around the urethra. As the first of the three "C"s, diverticula configuration may be described as solitary or multiloculated and as simple, saddle-shaped, or circumferential (Fig. 26-6). Preoperative delineation aids complete surgical excision. It also helps identify those requiring an interposition flap or needing ureteral catheter placement to delineate anatomy during dissection (Rovner, 2003).

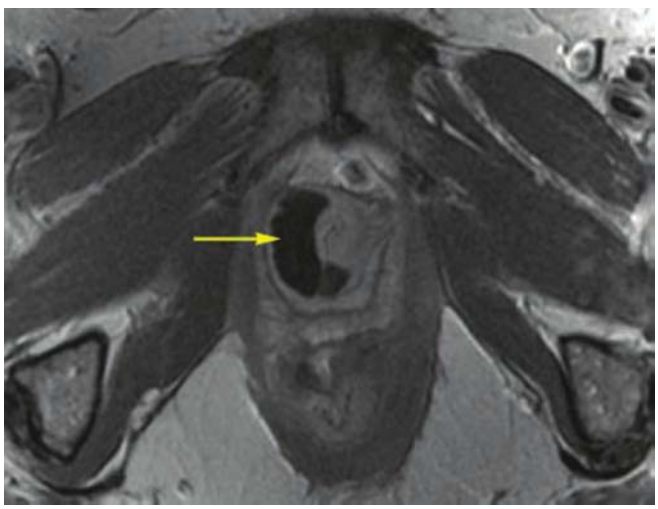

FIGURE 26-6 In this magnetic resonance image, a circumferential urethral diverticulum (*arrow*) is seen extending around the urethra.

Second, successful repair of the urethral wall defect depends in great part on locating the diverticular opening into the urethral canal. Thus, the communication site is sought preoperatively and classified as proximal, mid-, or distal urethral. In the previously cited study, midurethral communication sites were the most common (60 percent), followed by proximal (25 percent) and distal (15 percent) sites.

Finally, in the Leach system, the continence status and urethral hypermobility of the patient are documented. Almost half of the patients in Leach's series had stress urinary incontinence, and these authors suggest that urethral hypermobility is an indication for concomitant incontinence surgery. Several studies have documented the safety of performing concurrent antiincontinence surgery, mainly pubovaginal sling. However, some still consider this approach controversial because of urethral erosion concerns, especially with synthetic sling material (Enemchukwu, 2015; Ganabathi, 1994; Swierzewski, 1993). Although consensus is lacking on this issue, repairing the diverticulum first and then considering antiincontinence surgery if urinary incontinence persists is reasonable. This staged fashion is a particularly realistic option because of the current array of effective minimally invasive surgical procedures, such as midurethral slings. If a staged approach is elected, some suggest urodynamic testing prior to diverticulum repair. This establishes a continence baseline for later comparison.

SYMPTOMS

Urethral diverticula are frequently discovered incidentally during gynecologic or urologic examination. However, symptoms may vary and reflect diverticulum size, location, and extension. The classic triad is postvoid dribbling, dysuria, and dyspareunia. In addition, finger compression of a suburethral mass elicits egress of discharge from the diverticulum and into the urethra (Fig. 26-7).

Importantly, not all women present so classically. Romanzi and coworkers (2000) found pain in 48 percent of affected women. Pain most likely stems from cystic dilation and also possibly from concurrent inflammation. Baradaran and associates (2016) noted dyspareunia, stress urinary incontinence, recurrent urinary tract infections, and vaginal mass as primary findings. Those with dyspareunia may note either entry or deep dyspareunia, depending on diverticular location along the urethra.

A large diverticulum can sometimes be mistaken for early-stage pelvic organ prolapse, especially when the presenting complaint is vaginal fullness, bulge, or pressure. In these cases, the palpable diverticular vaginal mass may mimic a cystocele or rectocele. In most, careful systematic palpation of the vaginal wall will distinguish prolapse from a discrete vaginal wall cyst or diverticulum.

As described, lower urinary tract symptoms frequently accompany urethral diverticulum. Urinary incontinence is noted by 35 to 60 percent of affected women (Gabanathi, 1994; Romanzi, 2000). In addition, during micturition, urine may enter the diverticular sac, only to later spill from the sac and present as postvoid dribble or be misinterpreted

FIGURE 26-7 **A.** Urethral diverticulum seen in the anterior vaginal wall. **B.** Transurethral expression of discharge during its compression.

as urinary incontinence. Conversely, urinary retention also has been reported (Nitti, 1999). Retention frequently accompanies periurethral or diverticular sac cancers, discussed later. Urinary tract infection often complicates urethral diverticulum. In one review of 60 affected women, recurrent urinary tract infection was highly specific for urethral diverticula (Pathi, 2013).

Less frequently, stones may form from urine stagnation and salt precipitation within the diverticular sac. As such, stones may be singular or multiple and are usually composed of calcium oxalate or calcium phosphate. Approximately 10 percent of women with diverticula are affected (Perlmutter, 1993).

Malignant transformation within a urethral diverticulum is rare and accounts for only 5 percent of urethral cancers. Most of these tumors are adenocarcinomas, although transitional cell and squamous cell carcinomas have been identified (Clayton, 1992). Tumors typically present in the sixth or seventh decade of life, and hematuria, irritative voiding complaints, and urinary retention are common. Thus, palpation of an indurated or a solid, fixed periurethral mass typically prompts further diagnostic evaluation and tissue biopsy (Fig. 26-8) (von Pechmann, 2003). Given the few number of these cancers, codified treatment strategies are lacking. Currently, these malignancies are treated by anterior exenteration or by diverticulectomy, alone or with adjuvant radiation therapy (Shalev, 2002).

FIGURE 26-8 For this urethral mass, lidocaine was used, and directed biopsy using Tischler biopsy forceps was performed.

DIAGNOSIS

For many women, urethral diverticula may be diagnosed using a detailed history, physical examination, and high index of suspicion. Patient evaluation focuses on the common characteristics and symptoms noted earlier (p. 581). However, despite available clinical tools, the diagnosis for many women is delayed as they may initially be treated for stress or urgency incontinence, chronic cystitis, trigonitis, urethral syndrome, vulvovestibulitis, pelvic organ prolapse, and idiopathic chronic pelvic pain. Moreover, the diverticulum itself may mimic a Gartner duct cyst, müllerian remnant vaginal cyst, vaginal epidermoid inclusion cyst, ectopic ureterocele, or endometrioma.

Physical Examination

The most frequent physical finding, an anterior vaginal mass beneath or adjacent to the urethra, is detected in 50 to 90 percent of symptomatic patients (Ganabathi, 1994; Gerrard, 2003; Romanzi, 2000). Digital expression of purulent material during compression of the mass is not seen universally. Stenosis of the diverticular duct may obstruct sac emptying in these cases. Thus, meticulous examination and palpation is performed along the entire length of the urethra. Once diverticula are identified, their number, size, consistency, and configuration are determined.

Occasionally, physical examination alone may be insufficient to completely characterize a mass. Of ancillary tests, each has its advantages and disadvantages. Thus, familiarity with each modality's strengths aids selection of the most appropriate test for a given patient.

Cystourethroscopy

Of the diagnostic procedures used to detect urethral diverticula, cystourethroscopy is the only tool that allows direct inspection

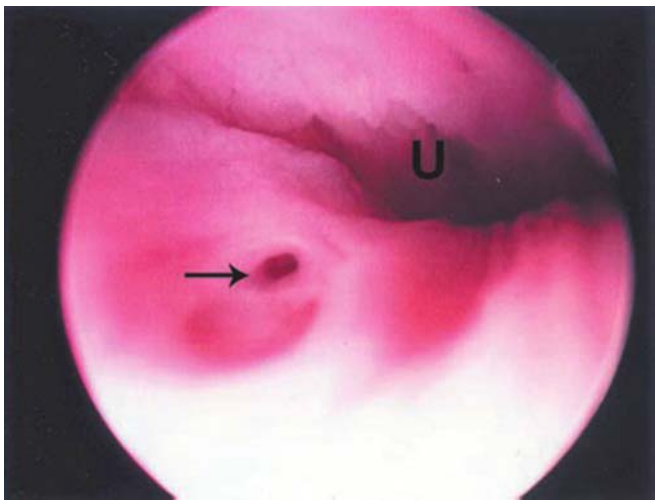

FIGURE 26-9 Diverticular opening visualized on cystourethroscopic examination (*arrow*). U = urethra.

of the urethra and bladder. During endoscopy, fingers pressed upward against the proximal anterior vaginal wall help occlude the bladder neck and allow the distending medium to create positive pressure that may open diverticular ostia (Fig. 26-9). A zero-degree cystoscope lens allows complete radial assessment of the urethra to aid identification of diverticular ostia and, at times, purulent discharge exuding from them.

A primary advantage to cystourethroscopy includes its accuracy for detecting diverticular ostia (Summitt, 1992). Moreover, in those with nonspecific lower urinary tract symptoms, other causes such as urethritis, cystitis, stones, or stenosis can be excluded. Despite these advantages and its common use by urogynecologists, gynecologic generalists employ cystourethroscopy less frequently. Obstacles include inexperience evaluating bladder and urethral mucosal anatomy, cystoscopic expertise, instrumentation costs, and credentialing challenges. Even for clinicians who are experienced with this tool, not all diverticular ostia are identified. For example, a poor seal between the cystoscope and distal urethral mucosa may lead to inadequate sac distention and failure to see very distally located diverticula. Also, narrow or stenotic diverticular ostia may not communicate with the urethral lumen and can be missed. Although cystourethroscopy is minimally invasive, patient pain and risk of postprocedural infection are additional considerations. Last, important information regarding diverticular size, number, and configuration may not be obtained with this tool.

Magnetic Resonance Imaging

This imaging modality has become the diagnostic standard to characterize periurethral masses because of its superior resolution of soft tissue. Specifically, for detecting urethral diverticula, magnetic resonance (MR) imaging has comparable or superior sensitivity compared with other radiologic techniques (Lorenzo, 2003; Neitlich, 1998). To improve resolution with MR imaging, an imaging coil housed inside a probe may be placed into the rectum. Instead, an external plate positioned on the lower abdomen can be used to similarly enhance resolution. Compared with the coil, the external plate is preferred by many institutions because its diagnostic accuracy is comparable but patient comfort is superior. Despite MR imaging's advantages, procedure costs are balanced against the need for additional anatomic information. For a solitary diverticulum with clearly demarcated boundaries and no evidence of extension, costly and extensive imaging may not be necessary.

Other Imaging Tools

We use the two previously mentioned techniques most commonly, and other techniques traditionally performed in the past are no longer routinely used at our institution for initial evaluation. Of these, a *voiding cystourethrogram (VCUG)* relies on radiographic contrast being instilled into the bladder and filling a diverticular sac during voiding. Radiographs are then obtained. This painless, simple test has an overall reported accuracy that approximates 85 percent. However, some prefer positive-pressure urethrography as a primary diagnostic tool, since VCUG requires a diverticular communication to be patent during testing (Blander, 2001). Moreover, VCUG involves ionizing radiation exposure for the patient, although the amount is small.

Positive pressure urethrography (PPUG) also uses radiographic contrast and x-ray. With PPUG, a double-balloon, triple-lumen catheter (Trattner catheter) is inserted through the urethra, and its tip enters the bladder (Fig. 26-10). Inflating the proximal balloon in the bladder allows it to be pulled snug against and occlude the urethra at the urethrovesical junction. A distal balloon obstructs the distal urethra. A single catheter port between the two balloons allows instillation of radiopaque contrast. Pressure from the contrast within the blocked urethra distends the urethral caliber and fills the diverticulum. For accurately identifying diverticula, PPUG has a sensitivity surpassing that of VCUG (Golomb, 2003). Disadvantageously, PPUG can be time-consuming, technically difficult, and associated with patient discomfort and postprocedural infection risk. Additionally, similar to VCUG, diverticula may be missed if

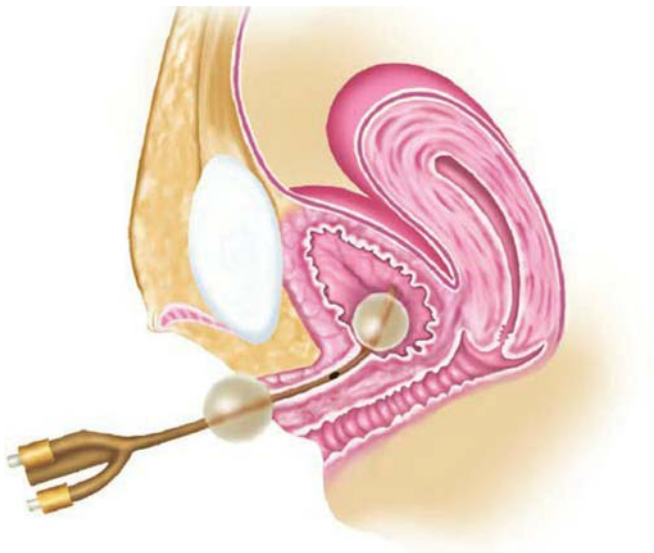

FIGURE 26-10 Trattner double-balloon catheter used to diagnose urethral diverticula.

thick exudate or debris prevents adequate filling with contrast medium or if the diverticular ostium is stenotic. Last, fewer radiologists are proficient with the technique, and Trattner catheters are not commonly not stocked in hospitals.

Sonography, especially with 3-dimensional rendering, is a relatively new modality for urethral diverticulum assessment and appears to have some efficacy (Gerrard, 2003). Suggested technical advantages include visualization of diverticula that do not fill during radiographic contrast studies and characterization of diverticular wall thickness, size, and internal architecture (Yang, 2005). Transabdominal, -vaginal, -rectal, -perineal, and -urethral sonographic techniques have been described (Keefe, 1991; Vargas-Serrano, 1997). Although the endourethral technique appears to have excellent specificity, it is expensive and may be more invasive that the other sonographic routes (Chancellor, 1995). Advantages of sonography include patient comfort, avoidance of ionizing radiation and contrast exposure, relative low cost, and reduced invasiveness. However, in addition to its learning curve, sonography's role in urethral diverticulum diagnosis has not been clearly established. Currently, it remains an academic, investigational, or adjunctive technique.

Because consensus is lacking on which primary modality is best, we begin with cystourethroscopic evaluation. If the initial evaluation is unrevealing but the diagnostic suspicion remains high or if the lesion appears more complex, then MR imaging is elected. Intravenous contrast and an external plate are added to help improve image resolution.

TREATMENT

Acute Treatment

A urethral diverticulum may acutely provoke pain, urinary symptoms, or focal tenderness during examination. Conservative management is initially recommended and includes sitz baths, oral analgesics, and a broad-spectrum antibiotic such as a cephalosporin or fluoroquinolone.

Chronic Diverticula

For a chronic diverticulum, a conservative approach may be elected by women who have few or no symptoms or who decline surgery due to its associated risks. Important surgical risks include urethrovaginal fistula, worsening or de novo urinary incontinence, altered voiding stream or pattern, and dyspareunia. For those electing observation, however, long-term data are lacking regarding rates of subsequent symptom development, diverticulum enlargement, or eventual need for surgical excision.

Many practitioners may deliberate as to whether an enlarged inflamed cystic connection with the urethra is termed an "inflamed Skene gland cyst" or a "urethral diverticulum." Pragmatically, for those with persistent bothersome symptoms the treatment is the same, with surgical intervention often indicated. Procedures include diverticulectomy, transvaginal partial ablation, and marsupialization. Each is described in Chapter 45 (p. 1106).

Of these, *diverticulectomy* is the most frequently chosen to treat diverticula at any site along the urethra. This involves excision of the entire diverticulum and closure of the ostium and communication into the urethra (Fig. 26-11). The technique provides long-term correction of the urethral defect, normal urine stream, and high rates of postoperative continence. However, disadvantages include risks for postsurgical urethral

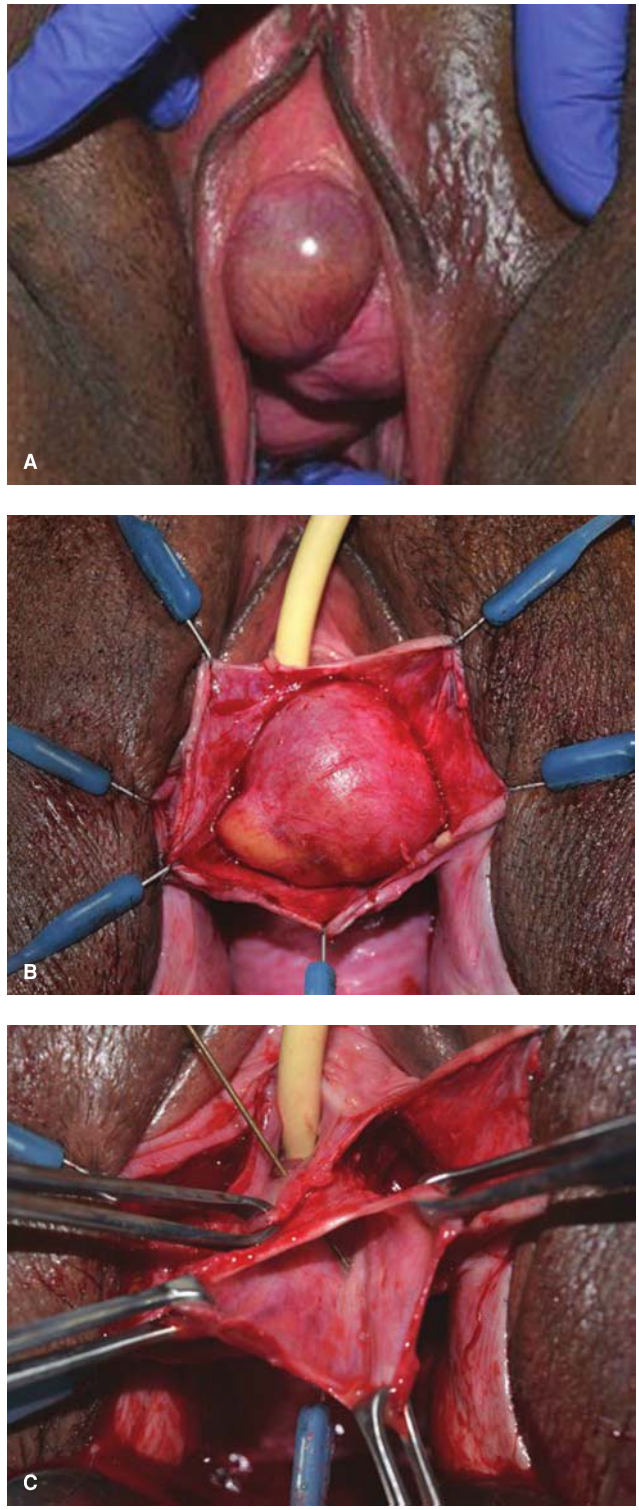

FIGURE 26-11 Diverticulectomy photographs. **A.** Urethral diverticulum. **B.** Anterior vaginal wall incised and self-retaining retractor used to expose the diverticulum. Foley catheter seen within the urethra. **C.** The diverticulum is opened. Passage of a lacrimal duct probe demonstrates the communication between the urethral lumen and the diverticular cavity.

stenosis, urethrovaginal fistula, injury to the urinary sphincter continence mechanism with subsequent incontinence, and recurrence. For patients who also have stress urinary incontinence, some practitioners recommend concomitant placement of either a midurethral or pubovaginal sling. As noted earlier, although this practice is supported by some studies, our preference is to approach it as a staged procedure (p. 581). We perform the defect repair first and later reassess the need for antiincontinence surgery.

Another surgery, *partial diverticular sac ablation,* may be preferred for proximal diverticula to avoid bladder entry or bladder neck injury. With this procedure, unneeded diverticular sac is excised, but the diverticular neck is not removed. Instead, the preserved diverticular sac tissue is reapproximated to close the defect (Tancer, 1983).

Last and less frequently, diverticulum marsupialization, also known as the Spence procedure, has been used for distal diverticula (Spence, 1970). The procedure is a meatotomy that when healed forms a new wider urethral meatus. Although simple to perform, this procedure alters the shape and function of the urethral meatus. Patients often note de novo spraying of their urine stream.

Other procedures described in case reports include urethroscopic transurethral electrosurgical fulguration of the diverticular sac and transurethral incision to widen the diverticular ostia (Miskowiak, 1989; Saito, 2000; Vergunst, 1996). Data are lacking, however, regarding long-term efficacy and complication rates with these techniques.

BIOLOGY OF CANCER GROWTH

In principle, chemotherapeutic drugs are able to treat cancer and spare normal cells by exploiting inherent differences in their individual growth patterns. Each tumor type has its own characteristics, which explains why the same chemotherapy regimen is not equally effective for the whole spectrum of gynecologic cancers. Selecting appropriate drugs and limiting toxicity demands an understanding of cellular kinetics and biochemistry.

The Cell Cycle

All dividing cells follow the same basic sequence for replication. The *cell generation* time is the time required to complete the five phases of the cell cycle (Fig. 27-1). The G_1 phase (G = gap) involves various cellular activities, such as protein synthesis, RNA synthesis, and DNA repair. When this is prolonged, the cell is considered to be in the G_0 phase, that is, the resting phase. G_1 cells may either terminally differentiate into the G_0 phase or reenter the cell cycle after a period of quiescence. During the S phase, new DNA is synthesized. The G_2 (premitotic) phase is characterized by cells having twice the DNA content as they prepare for division. Finally, actual mitosis and chromosomal division take place during the M phase.

Tumors do not typically have faster generation times. They instead have many more cells in the active phases of replication and have dysfunctional apoptosis (programmed cell death). In contrast, normal tissues have a much larger number of cells in the G_0 phase. As a result, cancer cells proceeding through the cell cycle may be more sensitive to chemotherapeutic agents, whereas normal cells in G_0 are protected. This growth pattern disparity underlies the effectiveness of chemotherapeutic agents.

Cancer Cell Growth

Tumors are characterized by a *gompertzian growth* pattern. Namely, a tumor mass requires progressively longer times to double in size as it enlarges. When a cancer is microscopic and nonpalpable, growth is exponential. However, as a tumor enlarges, the number of its cells undergoing replication decreases due to limitations in blood supply and increasing interstitial pressure.

When tumors are in the exponential phase of gompertzian growth, they should be more sensitive to chemotherapy because a larger percentage of cells are in the active phase of the cell cycle. For this reason, metastases should be more sensitive to chemotherapy than a large primary tumor. To capitalize on this potential benefit, advanced ovarian cancer is usually first treated with surgery to remove the primary tumor, debulk large masses, and leave only microscopic residual disease for the adjuvant chemotherapy to act on. In addition, when a tumor mass shrinks in response to treatment, the presumption is that a greater number of cells will enter the active phase of the cell cycle to accelerate growth. This larger percentage of replicating cells should also increase the sensitivity of a tumor to chemotherapy.

Doubling Time

The cell cycle generally refers to the activity of individual tumor cells. Instead, the *doubling time* refers to the time needed for the entire heterogeneous tumor mass to double in size. In humans, the doubling times of specific tumors vary greatly. The speed with which tumors grow and double in size is largely regulated by the number of cells that are actively dividing—known as the *growth fraction*. Typically, only a small percentage of the tumor will have cells that are rapidly proliferating. The remaining cells are in the G_0 resting phase. In general, tumors that are cured by chemotherapy are those with a high growth fraction, such as gestational trophoblastic neoplasia. When tumor volume is reduced by surgery or chemotherapy, the remaining tumor cells are theoretically propelled from the G_0 phase into the more vulnerable phases of the cell cycle, rendering them susceptible to chemotherapy.

Cell Kinetics

Chemotherapeutic agents typically work by first-order kinetics to kill a constant *fraction* of cells rather than a constant

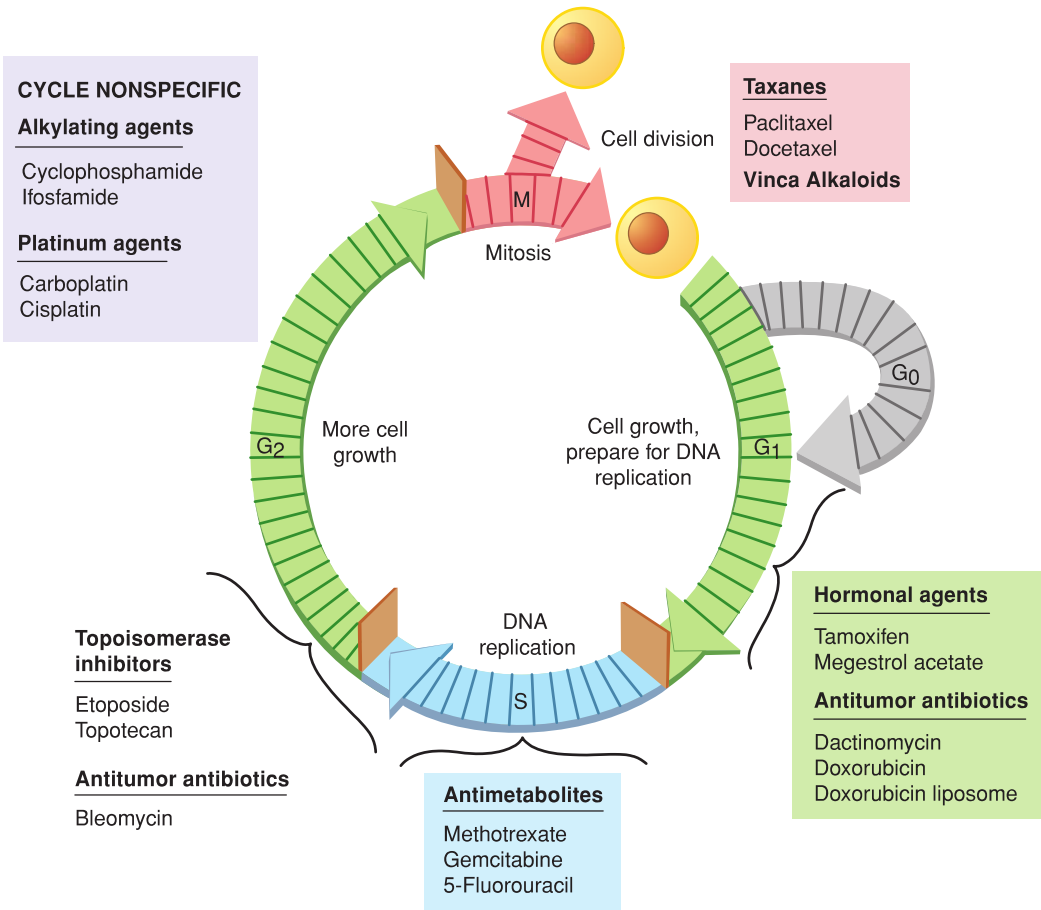

FIGURE 27-1 Diagram of the cell cycle. Agents are organized according to the cell cycle stage in which they are most effective for tumor control.

number. For example, one dose of a cytotoxic drug may result in a few logs (10^2 to 10^4) of cell kill. This, however, is not curative since tumor burden may be 10^{12} cells or more. Thus, the magnitude of cell kill necessary to eradicate a tumor typically requires intermittent courses of chemotherapy. In general, a cancer's curability is inversely proportional to the number of viable tumor cells at the beginning of chemotherapy.

Some drugs achieve cell kill at several phases of the cell cycle. These *cell cycle–nonspecific* agents act in all phases of replication from G_0 to the M phase. *Cell cycle–specific* agents act only on cells that are in a specific phase. By combining drugs that act in different phases of the cell cycle, the overall cell kill should be enhanced.

CLINICAL USE OF CHEMOTHERAPY

Clinical Setting

Chemotherapy may be used in at least five different ways. The term *induction chemotherapy* is defined as primary treatment for patients with an advanced malignancy when no feasible alternative treatment exists. *Adjuvant chemotherapy* is given to destroy remaining microscopic cells that may be present after the primary tumor is removed by surgery. *Neoadjuvant chemotherapy* refers to drug treatment directed at an advanced cancer to decrease preoperatively the extent or morbidity of a subsequent surgical resection. *Consolidation* (or *maintenance*) *chemotherapy* is given after cancer has disappeared following the initial therapy and aims to prolong the duration of clinical remission or to prevent ultimate relapse. Therapy applied to recurrent disease or to a tumor that is refractory to initial treatment is termed *salvage* (or *palliative*) *chemotherapy*. In these incurable patients, the intent is to achieve tumor shrinkage or stability yet maintain quality of life.

In general, chemotherapy is used with either curative or palliative intent. When implementing chemotherapy with curative intent, the number of courses is typically predefined. Emphasis is placed on maintaining curative dosages and adhering closely to the treatment schedule. This may lead to significant toxicity and require growth-factor support to counter anemia or neutropenia. However, for the possibility of achieving cure, these side effects are typically deemed acceptable.

Chemotherapy is often not used with curative intent but is instead applied for effective, compassionate palliation. In this setting, greater importance is attached to avoiding excessive toxicity. Rather than a defined number of treatment courses, a clinician must frequently revisit treatment efficacy and alter the dosage and timing of chemotherapy administration accordingly.

Drug Regimens

With few exceptions, single drugs administered at clinically tolerable doses do not cure cancer. However, using two or more

drugs simultaneously may greatly exacerbate toxicity. Thus, in principle, the goal of combination chemotherapy is to provide maximum cell kill with minimal or tolerable adverse patient side effects. Drugs are selected based on their proven efficacy as single agents, differing mechanisms of action, and toxicities that overlap minimally or not at all.

Combination chemotherapy is more effective in attacking heterogeneous populations of cells. Moreover, the use of multiple drugs with differing mechanisms tends to minimize the emergence of drug resistance. Typically, drugs used in combination should have clinical data indicating that their effects will be synergistic or at least additive. Drugs in combination are used at their optimal doses and schedules. Dose reductions initiated solely to allow the addition of other agents are counterproductive because most drugs must be used near their maximum tolerated dose to ensure efficacy.

Frequently, chemotherapy is combined with radiation therapy or sequenced with surgery. The goal of *chemoradiation* is to achieve local control by chemically rendering the tumor more sensitive to radiation. For example, care of locally advanced cervical cancer was transformed by adding weekly cisplatin to standard radiotherapy. In addition, concurrent chemotherapy is intended to treat micrometastases outside the radiation field.

However, patients recently treated with radiation therapy may have bone marrow, skin, or other body systems that are more susceptible to chemotherapy toxicity. As a result, dose reductions or delays are commonplace. Furthermore, chemotherapy is generally less effective in tumors that lie within a previously irradiated field due to increased fibrosis and capillary destruction.

Combining chemotherapy with surgery has many different applications. A woman with endometrial cancer may have nodal metastases detected during surgery. She may then receive pelvic radiation preceded or followed by combination chemotherapy. Alternatively, a woman with recurrent ovarian cancer may be treated by combination chemotherapy with or without preceding secondary cytoreductive surgery. Sequencing treatment in this way reduces tumor bulk and thereby augments chemotherapy effectiveness. In general, adjunctive therapy is begun within a few weeks after surgery. The short delay allows surgical healing.

Directing Care of the Patient

To effectively counsel a gynecologic cancer patient and then guide her chemotherapeutic treatment course requires a comprehensive understanding of the diagnosis, alternatives, and goals of care. As the intended therapy is finalized, extensive information regarding anticipated side effects and clarification of all potential logistical challenges (e.g., intravenous access) is provided to allay concerns. A consent form must be reviewed and signed by the patient.

Prior to drug infusion, a complete medical history and comprehensive physical examination are mandatory. Blood work, including a complete blood count, comprehensive metabolic panel, and tumor markers as indicated, is performed and reviewed before orders to begin infusion are signed. The setting for drug administration must provide staff that are immediately available should the need arise. Afterward, the patient is provided contact numbers in case of questions or problems.

Typically, regular office visits shortly before or on the day of treatment allow assessment of toxicity and general health. Patient examination and review of blood work results, in the context of the tumor response and overall treatment goals, will help determine whether drugs are changed or their dosages revised. Over time, the treatment strategy is continually reassessed as circumstances change.

PHARMACOLOGIC PRINCIPLES

Dosing and Dose Intensity

Overall, treatment effectiveness depends on drug concentration and duration of exposure to critical tumor sites. Chemotherapeutic agents typically have a narrow therapeutic range or "window." Thus, doses must be calculated accurately to achieve an optimal effect above a critical threshold yet avoid undue toxicity.

Most commonly, chemotherapy doses are calculated based on the patient's body surface area (BSA), and doses are expressed in milligrams per meter squared (mg/m^2). BSA uses height and weight and is a better indicator of metabolic mass than body weight because it is less affected by abnormal adipose mass. Although height is a fixed variable, patient weights are obtained prior to every therapy course, as they may fluctuate significantly. Rarely, tissue edema or ascites must be factored, since doses should be based on weight without this coexisting fluid. The BSA is most often calculated by using a nomogram (standard reference graph table). Consistent derivation of the BSA at each visit is important, and various calculators are routinely available via software or online. "Normal" adult BSA for women approximates 1.7 m^2.

The dosing of some drugs differs from the above. For example, bevacizumab is a monoclonal antibody metabolized and eliminated via the reticuloendothelial system. It is dosed only by patient weight (mg/kg). For renally excreted drugs, such as carboplatin, dosing may be based on an estimate of the glomerular filtration rate (Calvert formula).

The amount of drug administered over time is known as the dose intensity. Its primary importance is in highly responsive tumors, in which cure can be achieved with chemotherapy. However, in less-sensitive tumors, it may not be possible to increase the dose to a level sufficient to produce demonstrable benefit without producing dose-limiting toxicity. On the other hand, reducing dose intensity to lower toxicity can produce inferior therapeutic results.

Administration Route and Excretion

In gynecologic oncology, chemotherapy drugs are provided orally in an increasing number, rarely subcutaneously (SC), and occasionally intramuscularly (IM). Most are given by an intravenous (IV) route. During IV administration, several drugs known as *vesicants* require special care (Table 27-1). Extravasation of these into the subcutaneous tissue can result in severe pain and necrosis. These drugs require slow infusion either through a rapidly flowing peripheral IV catheter or preferably via a central venous catheter. If extravasation is suspected, the infusion is immediately stopped, the affected arm elevated, and ice packs applied. In severe cases, a plastic surgeon is consulted.

TABLE 27-1. Chemotherapeutic Agents and Their Association with Extravasation Injury

Vesicants	Exfoliants	Irritants	Inflammants	Neutral
Dactinomycin Doxorubicin Paclitaxel	Cisplatin Docetaxel Liposomal doxorubicin Topotecan	Carboplatin Etoposide	Methotrexate	Bleomycin Cyclophosphamide Gemcitabine Ifosfamide

Vesicant, agent capable of causing skin ulceration and tissue necrosis on extravasation; *exfoliant*, agent capable of causing skin exfoliation on extravasation; *irritant*, agent capable of causing skin irritation on extravasation; *inflammant*, agent capable of causing skin inflammation on extravasation.

Regional chemotherapy delivers drugs directly into the cavity in which the tumor is located. Clearance for many agents from a body cavity is slower than from systemic circulation. As a result, cancer cells are exposed longer to higher concentrations of active agents. This technique has been most extensively studied in ovarian cancer, in which tumors are usually confined to the intraperitoneal (IP) space. Clinical studies have uniformly demonstrated a pharmacologic advantage favoring administration into the IP compartment. However, penetration into peritoneal tumor nodules by passive diffusion can be limited by intraabdominal adhesions, poor fluid circulation, fibrotic tumor encapsulation, and coexisting ascites. Because of these limitations in drug penetration, IP chemotherapy is typically administered postoperatively to women with minimal residual disease. As a variation, heated chemotherapy may further improve absorption by tumors and destroy microscopic cancer cells. Hyperthermic intraperitoneal chemotherapy (HIPEC) involves heating the solution and circulating it throughout the abdomen for 1.5 hours at the completion of debulking surgery. The solution is then drained before closing the incision.

Drug inactivation, elimination, or excretion dramatically influences activity and toxicity. For the most part, this takes place primarily via the liver or kidneys. As a result, drug activity may be diminished and toxicity exacerbated when normal hepatic or renal function is impaired. In addition, drug toxicity is often more pronounced in the elderly or malnourished. For example, a low serum creatinine level in cachectic women may not accurately reflect underlying renal function. If a carboplatin dose is calculated using this falsely low value, the amount may be excessive and result in considerable morbidity. Instead, a preset creatinine level may need to be selected (0.8 or 1.0 mg/dL) to aid safer dosing in some patients.

Drug Interactions and Allergic Reaction

Most women who receive chemotherapy are prescribed medication for other noncancerous conditions. Moreover, women also often receive analgesics, antiemetics, and antibiotics during chemotherapy. Most drug interactions are of little consequence, but some may lead to substantially altered drug toxicity. Drugs that are metabolized in the liver are particularly at risk for such interactions. For example, using methotrexate in a woman taking warfarin (Coumadin) will usually enhance the anticoagulant effect and thus will require a warfarin dose reduction.

An anaphylactic, allergic, or hypersensitivity reaction during or after administration of chemotherapy may develop, despite patient history review and administration of prophylactic medications. Accordingly, a trained nursing staff and resources to manage these sudden, but common, issues are required. Prior to drug administration, the patient is instructed to report symptoms that may herald an anaphylactic reaction such as flushing, pruritus, dyspnea, tachycardia, hoarseness, or lightheadedness. Emergency equipment that includes supplemental oxygen, ventilatory face mask and bag, or intubation equipment must be immediately available. For a localized hypersensitivity response, administration of intravenous diphenhydramine (Benadryl) and/or corticosteroids may be sufficient. However, for a generalized hypersensitivity or anaphylactic response, chemotherapy should be stopped immediately, the emergency team notified, and emergency drugs administered, such as epinephrine (1 to 5 mL of a 0.1/mL solution [1:10,000 solution]) (Table 27-2).

Drug Resistance

In principle, larger tumor masses have a greater proportion of cells that have already developed intrinsic or acquired resistance to one drug or to multiple agents. Intrinsic drug resistance is seen if tumors are first exposed to an agent and fail to respond. In contrast, with acquired drug resistance, tumors no longer respond to drugs to which they were initially sensitive. Sometimes, this develops with a specific drug. More often, however, acquired resistance is "pleiotropic," meaning that a cancer is resistant to multiple chemotherapy agents. Advanced ovarian cancer is a good example. Most patients will initially achieve remission with platinum-based chemotherapy, but 80 percent will ultimately relapse and die from tumors that have become resistant to all cytotoxic therapy.

Evaluating Response to Chemotherapy

The effective use of chemotherapy is a dynamic process in which a treating clinician is constantly weighing toxicity to the patient against tumor response. In counseling women to continue treatment or switch to a different regimen, a clinician must have objective criteria for response (Table 27-3) (Eisenhauer, 2009).

TABLE 27-2. Management of Hypersensitivity Reactions

1. Stop the chemotherapy infusion
2. Assess the patient's airway, breathing, and circulation
3. Administer intravenous normal saline if hypotensive
4. Administer oxygen if dyspneic or hypoxic
5. Administer intravenous antihistamine (e.g., 50 mg intravenous diphenhydramine or 25–50 mg intravenous promethazine)
6. Administer 5 mg of nebulized salbutamol if the patient has bronchospasm
7. Administer intravenous corticosteroids (e.g., 100 mg of hydrocortisone); this may have no effect on the initial reaction, but may prevent rebound or prolonged allergic manifestations
8. If the patient does not promptly improve or has symptoms of persistent or severe hypotension or persistent bronchospasm or laryngeal edema, administer adrenaline or epinephrine (0.1–0.25 mg intravenous); further acute resuscitation measures may be required
9. Reassure the patient that the problem is a recognized and treatable one

Adapted with permission from Gershenson DM, McGuire WP, Gore M, et al (eds): Gynecologic Cancer Controversies in Management. Philadelphia, Elsevier, 2004.

The most important indicator is the *complete response rate*. For ovarian cancer, this would include normal CA125 levels (usually <35 U/mL), physical examination findings, and imaging test results. Ultimately, women who have any possibility of cure are those who first achieve a complete response. However, if chemotherapy results in a partial response, many women still view this as advantageous compared with supportive care, even if a survival benefit is unproven.

CHEMOTHERAPEUTIC DRUGS

Antimetabolites

The antimetabolites are analogues of naturally occurring components of the metabolic pathways that lead to the synthesis of purines, pyrimidines, and nucleic acids. In most cases, they are S phase–specific agents that are most effective in rapidly growing tumors associated with short doubling times and large growth fractions (Table 27-4).

Methotrexate

This antimetabolite is U.S. Food and Drug Administration (FDA)-approved for treatment of women with gestational trophoblastic neoplasia (GTN). It is also commonly used for the medical management of ectopic pregnancy. Methotrexate (MTX) tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolate (the active form of folic acid) (Fig. 27-2). As a result, thymidylate synthetase and various steps in de novo purine synthesis are halted. This leads to arrest of DNA, RNA, and protein synthesis.

Most commonly, single-agent treatment of GTN involves MTX given IM as an 8-day regimen of 1 mg/kg on treatment days 1, 3, 5, and 7. Alternatively, a daily dose of 0.4 mg/kg is given for 5 days every 2 weeks. Combination therapy for high-risk disease includes 100 mg/m^2 MTX given IV over 30 minutes, followed by a 200 mg/m^2 IV dose over 12 hours. With MTX, patients are counseled to avoid folate-containing supplements unless specifically directed.

MTX causes few side effects at typical doses. However, at high doses, although used infrequently, this agent can lead to fatal bone marrow toxicity. This toxicity can be prevented by "rescue" doses of leucovorin. Leucovorin is folinic acid, has activity that is equivalent to folic acid, and thus is readily converted to tetrahydrofolate. Leucovorin, however, does not require dihydrofolate reductase for its conversion. Therefore, its function is unaffected by inhibition of this enzyme by MTX. Leucovorin administration, therefore, allows for some purine and pyrimidine synthesis. Leucovorin rescue is incorporated into the 8-day alternating MTX schedule, and a 0.1-mg/kg leucovorin dose is provided orally on treatment days 2, 4, 6, and 8.

In addition to myelosuppression, renal toxicity and acute cerebral dysfunction are typically only seen at high MTX doses. Methotrexate is predominantly excreted through the kidneys, and thus women with renal insufficiency have doses reduced. Serum MTX levels are carefully monitored in these patients, as they may require prolonged leucovorin rescue.

TABLE 27-3. Clinical End Points in Evaluating Response to Chemotherapy

End Point	Definition
Complete response (CR)	Disappearance of all measurable "target" lesions
Partial response (PR)	A decrease of ≥30% in the sum of diameters of all target lesions
Progressive disease (PD)	An increase of ≥20% in the sum of diameters of target lesions or the identification of one or more new lesions
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR, nor sufficient increase to qualify for PD

TABLE 27-4. Chemotherapy Antimetabolites Used for Gynecologic Cancer

Generic Name	Brand Name	Indications	Routes	Common Dosages	Common Toxicity
Methotrexate	Trexall, Rheumatrex	GTN	PO, IM, IV, intrathecal	IM: 1 mg/kg on days 1, 3, 5, 7 or 0.4 mg/kg on days 1–5, every 2 wk IV: 100 mg/m^2 during 30 min, then 200 mg/m^2 during 12 hr	BMD, mucositis, renal toxicity, CNS dysfunction
Gemcitabine	Gemzar	Recurrent ovarian CA, uterine sarcoma	IV	600–1250 mg/m^2/wk over 30 min × 2–3 wk	BMD, N/V/D, malaise and fever
5-Fluorouracil	Adrucil	Cervical CA, vulvar CA	IV	800–1000 mg/m^2/d during 96 hr	Mucositis, PPE
	Efudex	VAIN	Vaginal cream	3 mL QOD × 1 wk, then weekly up to 10 wk	Vulvovaginal irritation

BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PPE = palmar-plantar erythrodysesthesia; PO = orally; QOD = every other day; VAIN = vaginal intraepithelial neoplasia.

Gemcitabine

This antimetabolite is FDA approved to be used with other agents for treatment of recurrent ovarian cancer but is also commonly used for uterine sarcoma. Gemcitabine (Gemzar) is a synthetic nucleoside analogue that undergoes multiple phosphorylations to form the active metabolite. The resulting triphosphate is subsequently incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one additional deoxynucleotide is added to the end of the DNA chain before replication is terminated, and DNA synthesis is thereby halted.

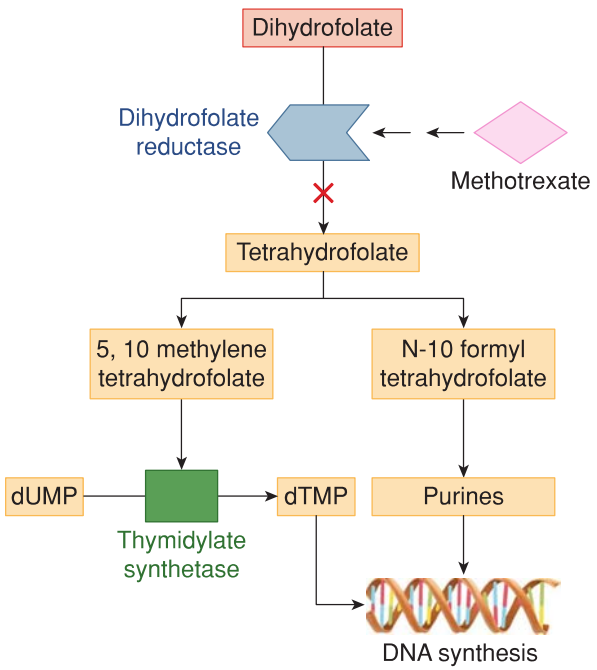

FIGURE 27-2 Methotrexate's primary target is the enzyme dihydrofolate reductase (DHFR). Inhibition of DHFR leads to partial depletion of 5,10 methylene tetrahydrofolate and N-10 formyl tetrahydrofolate, which are cofactors required for the respective synthesis of thymidylate and purines. As a result, methotrexate leads to arrested DNA, RNA, and protein synthesis. dTMP = deoxythymidine monophosphate; dUMP = deoxyuridine monophosphate.

The usual administration of gemcitabine is by 30-minute infusion. Longer durations, such as those greater than 60 minutes, are associated with increased toxicity due to intracellular accumulation of the triphosphate. Depending on whether it is used as a single agent or in combination, gemcitabine is typically given at doses between 600 and 1000 mg/m^2 once weekly for 2 weeks, followed by a week off therapy.

Myelosuppression, especially neutropenia, is the main dose-limiting side effect. Gastrointestinal (GI) toxicity, such as nausea, vomiting, diarrhea, or mucositis, also is common. Approximately 20 percent of patients will develop a flulike syndrome, including fever, malaise, headache, and chills. Pulmonary toxicity is infrequent, but reported.

5-Fluorouracil

5-Fluorouracil (5-FU) is not FDA approved for gynecologic cancer but is occasionally paired with cisplatin during chemoradiation for cervical cancer. A topical form (Efudex) can be used for vaginal intraepithelial neoplasia (VAIN) treatment (Chap. 29, p. 642). This "false" pyrimidine antimetabolite acts principally as a thymidine synthetase inhibitor to block DNA replication.

Systemic 5-FU (Adrucil) is usually given as a 96-hour continuous IV infusion of 800 to 1000 mg/m^2/d. Mucositis and/or diarrhea may be severe and dose-limiting. Hand-foot syndrome (palmar-plantar erythrodysesthesia), described later, is less common but also can be dose-limiting (p. 596). Myelosuppression, mainly neutropenia and thrombocytopenia, are less frequent. Nausea and vomiting are usually mild.

TABLE 27-5. Chemotherapy Alkylating Agents Used for Gynecologic Cancer

Generic Name	Brand Name	Indication	Routes	Dosages	Toxicity
Cyclophosphamide	Cytoxan	GTN, recurrent ovarian CA	PO, IV	IV: 500–750 mg/m^2 over 30 min, every 3 wk PO: 50 mg/d	BMD, cystitis, N/V, alopecia
Ifosfamide	Ifex	Recurrent ovarian CA, cervical CA, uterine sarcoma	IV	1.2–1.6 g/m^2/d, days 1–3 of 3-wk cycle	BMD, cystitis, N/V, alopecia, CNS and renal toxicity

BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IV = intravenous; N/V = nausea and vomiting; PO = orally.

Alkylating Agents

Cyclophosphamide

The class of alkylating agents is characterized by positively charged alkyl groups that bind to negatively charged DNA to form adducts (Table 27-5). Binding leads to DNA breaks or cross-links and a halt to DNA synthesis. In general, these drugs are cell cycle–nonspecific agents.

Of alkylating agents, cyclophosphamide (Cytoxan) is FDA approved by itself or in combination for epithelial ovarian cancer treatment. Cyclophosphamide is the "C" of EMA-CO (etoposide, methotrexate, actinomycin D, cyclophosphamide, Oncovin [vincristine]), which is a regimen prescribed for high-risk GTN. It is also used as salvage therapy for recurrent epithelial ovarian cancer (Bower, 1997; Cantu, 2002). Cyclophosphamide is a derivative of nitrogen mustard and is activated through a multistep process by microsomal enzymes in the liver. It promotes DNA cross-linking and DNA synthesis inhibition.

It is typically given IV at doses of 500 to 750 mg/m^2 over 30 minutes every 3 weeks. Orally, a metronomic (repetitive low-dose) regimen of 50 mg daily is often used to minimize toxicity and target the tumor endothelium or stroma in combination with a biologic agent, such as bevacizumab (Chura, 2007).

Myelosuppression, mainly neutropenia, is the usual dose-limiting side effect. Cyclophosphamide is excreted exclusively by the kidneys. One of its metabolites, acrolein, can alkylate and inflame the bladder mucosa. As a result, hemorrhagic cystitis is a classic complication that may follow from 24 hours to several weeks after administration. To prevent this effect, adequate hydration is imperative to aid acrolein excretion. In addition, GI toxicity, such as nausea, vomiting, or anorexia, is common. Alopecia is typically severe. Moreover, later secondary malignancy rates are increased, particularly acute myelogenous leukemia and bladder cancer.

Of chemotherapeutic drugs, alkylating agents are believed to be particularly damaging to ovarian function. Preventatively, adjuvant gonadotropin-releasing hormone (GnRH) agonists may lower rates of chemotherapy-induced ovarian failure, although the efficacy of this approach remains controversial (Chen, 2011; Elgindy, 2013). Importantly, advances in oocyte and ovarian tissue cryopreservation make it likely that the removal of oocytes prior to treatment will become the preferred approach when feasible (Chap. 21, p. 468).

Ifosfamide

This alkylating agent is not FDA approved for gynecologic cancers but is occasionally administered for salvage treatment of cervical cancer and uterine sarcoma. Ifosfamide (Ifex) is a structural analogue of cyclophosphamide, differing only slightly. However, its metabolic activation occurs more slowly and leads to a greater production of chloracetaldehyde, a possible neurotoxin.

Ifosfamide is administered IV, usually as a short infusion. Common doses of 1.2 to 1.6 g/m^2 are given on days 1 through 3 of a 3-week cycle. As with cyclophosphamide, adequate hydration is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. In addition, concurrent mesna (Mesnex) is used to prevent severe hematuria. A mesna metabolite chemically binds with acrolein, an ifosfamide metabolite, and detoxifies acrolein in the bladder. Other side effects are similar to those of cyclophosphamide. However, neurotoxicity, manifested as lethargy, confusion, seizure, ataxia, hallucinations, and occasionally coma, is more likely. These symptoms are caused by the chloracetaldehyde metabolite and are reversible with removal of the drug and supportive care. The incidence of neurotoxicity is higher in the rare patient receiving high-dose therapy and also in those with impaired renal function. With the latter, a preventive dose reduction is typically necessary.

Antitumor Antibiotics

Dactinomycin

The antitumor antibiotics are generally derived from microorganisms. Most antitumor antibiotics exert their cytotoxic effects by DNA intercalation during multiple phases of the cell cycle. They are considered cell cycle specific.

In this group, dactinomycin is FDA approved to treat GTN as a single agent or as part of combination chemotherapy (Table 27-6). Dactinomycin (Cosmegen), also known as actinomycin D, is the "A" of the EMA-CO chemotherapy combination. Dactinomycin becomes anchored into purine-pyrimidine DNA base pairs, resulting in DNA synthesis inhibition. It also produces toxic oxygen free radicals that cause DNA breaks. Dactinomycin is excreted mainly through the biliary system.

The usual "pulse" dosage of dactinomycin is 1.25 mg IV push every other week, but it is sometimes administered as a 0.5-mg dose on days 1 through 5 every 2 to 3 weeks. Myelosuppression is the main dose-limiting side effect and may be severe.

TABLE 27-6. Chemotherapeutic Antibiotics Used for Gynecologic Cancer

Generic Name	Brand Name	Indication	Route	Dosage	Toxicity
Actinomycin D (dactinomycin)	Cosmegen	GTN	IV	1.25 mg IV push every other wk or 0.5 mg on days 1–5, every 2–3 wk	BMD, N/V/D, alopecia, vesicant
Bleomycin	Blenoxane	Germ cell or SCST ovarian CA, GTN	IV, IM, SC, intrapleural	IV: 20 U/m^2 (maximum dose of 30 U), every 3 wk	Pulmonary toxicity, fever, skin reaction
Doxorubicin	Adriamycin	Uterine sarcoma, recurrent epithelial ovarian CA	IV	45–60 mg/m^2 every 3 wk	BMD, cardiac toxicity, alopecia, vesicant
Liposomal doxorubicin	Doxil	Recurrent epithelial ovarian CA	IV	40–50 mg/m^2 over 30 min, every 4 wk	PPE, stomatitis, infusion reaction

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PPE = palmar-plantar erythrodysesthesia; SC = subcutaneous; SCST = sex cord-stromal tumor.

Moreover, GI toxicity, including nausea, vomiting, mucositis, and diarrhea, is often significant. Alopecia is common. As with others in the antibiotic group, dactinomycin is a potent vesicant (see Table 27-1).

Bleomycin

This antitumor antibiotic is FDA approved for malignant pleural effusion treatment or for palliative therapy of recurrent squamous cervical or vulvar cancer. An off-label use includes bleomycin as the "B" in BEP (bleomycin, etoposide, cisplatin) regimens, which are used as adjuvant treatment of malignant ovarian germ cell or sex cord–stromal tumors (Park, 2012; Weinberg, 2011). Additionally, it is used in GTN salvage treatment (Alazzam, 2016). Bleomycin (Blenoxane), when complexed with iron, creates activated oxygen free radicals, which cause DNA strand breaks and cell death. It is maximally effective during the G_2 phase.

The usual dosage of bleomycin is 20 units/m^2 given IV every 3 weeks. Bleomycin can also be administered IM, SC, or intrapleurally. The dose is quantified by international units of "cytotoxic activity."

Pulmonary toxicity is the main dose-limiting side effect, developing in 10 percent of patients and causing death in 1 percent. Accordingly, for women prescribed bleomycin, chest radiographs and pulmonary function tests (PFTs) are performed at baseline and obtained regularly before every one or two treatment cycles. The most important PFT measurement is the diffusing capacity of the lung for carbon monoxide (DLCO). The DLCO measures the ability to transfer oxygen from the lungs to the blood stream. If the DLCO declines by 15 to 30 percent, it indicates development of restrictive lung disease. In patients receiving bleomycin, therapy may then be stopped before the onset of symptomatic pulmonary fibrosis. Fibrosis often presents clinically as pneumonitis with cough, dyspnea, dry inspiratory crackles, and infiltrates on chest radiograph. Bleomycin is not myelosuppressive. However, skin reactions are common and include hyperpigmentation or erythema.

Doxorubicin

This antitumor antibiotic is FDA approved to treat epithelial ovarian cancer, but doxorubicin (Adriamycin) is more frequently used for uterine sarcoma (Hyman, 2014; Mancari, 2014). This agent intercalates into DNA to inhibit DNA synthesis, inhibits topoisomerase II, and forms cytotoxic oxygen free radicals. The drug is metabolized extensively in the liver and eliminated through biliary excretion.

The usual dose of doxorubicin is 45 to 60 mg/m^2 IV, repeated every 3 weeks. Myelosuppression, particularly neutropenia, is the main dose-limiting side effect. However, cardiotoxicity is a classic complication. Patients are monitored with a multiple-gated acquisition (MUGA) radionuclide scan at baseline and periodically during therapy. The risk of cardiotoxicity is higher in women older than 70 and those with cumulative doses exceeding 550 mg/m^2. Ultimately, women may develop an irreversible dilated cardiomyopathy associated with congestive heart failure. Gastrointestinal toxicities are generally mild, but alopecia is universal.

Doxorubicin Liposome

This antitumor antibiotic is FDA approved and commonly used for the salvage treatment of recurrent epithelial ovarian cancer (Gordon, 2004). The liposomal encapsulation of doxorubicin (Doxil) dramatically alters the pharmacokinetic and toxicity profiles of the drug. Researchers developed liposomal doxorubicin to reduce cardiotoxicity and to selectively target tumor tissues.

Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes and is dosed at 40 to 50 mg/m^2 every 4 weeks. In contrast to doxorubicin, administration of the encapsulated liposome is associated with minimal nausea, vomiting, alopecia, and cardiotoxicity. Infusion-related reactions develop in less than 10 percent of patients and are most common during the first treatment course. However, an increased rate of stomatitis and palmar-plantar erythrodysesthesia (PPE) is noted.

FIGURE 27-3 Erythematous plaques of palmar-plantar erythrodysesthesia (PPE) on the lateral aspect of the abdomen.

PPE is characterized by a cutaneous reaction of varying intensity (Fig. 27-3). Patients may initially complain of tingling sensations on their soles and palms that generally progress to swelling and tenderness to touch. Erythematous plaques typically develop that can become extremely painful and often lead to desquamation and skin cracking. Symptoms result from the prolonged blood levels of this time-released cytotoxic agent and may last several weeks.

Plant-Derived Agents

Taxanes

The cytotoxic activity of all the plant-derived agents stems from the disturbance of normal assembly, disassembly, and stabilization of intracellular microtubules to halt cell division during mitosis (Fig. 27-4). The group includes the taxanes, vinca alkaloids, and topoisomerase inhibitors.

Of the taxanes, paclitaxel and docetaxel are both cell cycle–specific agents that have maximal activity during the M phase (Table 27-7). Derived from yew tree species, they act to "poison" the mitotic spindle by preventing depolymerization of the microtubules and inhibiting cellular replication.

Paclitaxel. This agent is FDA approved for the treatment of primary or recurrent epithelial ovarian cancer. It is also extensively used for endometrial cancer, cervical cancer, and occasionally GTN.

Paclitaxel (Taxol) is typically administered IV as a 3-hour infusion but may also be given as an intraperitoneal (IP) dose. The usual IV dosage is 135 to 175 mg/m^2 every 3 weeks. Weekly paclitaxel is also effective in a regimen of 80 mg/m^2 IV for 3 consecutive weeks on a 21-day schedule for primary disease or on a 28-day schedule for recurrent disease (Katsumata, 2009; Markman, 2006). For initial therapy of optimally debulked ovarian cancer following a day 1 IV dose, paclitaxel is usually given IP on day 8 at a dose of 60 mg/m^2 (Armstrong, 2006).

Myelosuppression is the usual dose-limiting side effect. Additionally, a hypersensitivity reaction occurs in approximately one third of patients due to its formulation in Cremophor-EL,

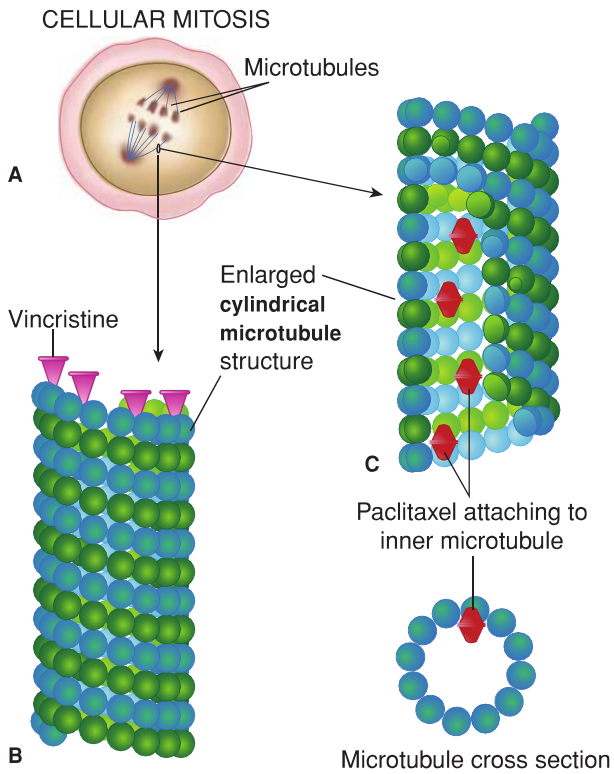

FIGURE 27-4 Diagram of taxane's and vinca alkaloid's mechanism of action. Parts B and C show magnified microtubule structure. **A.** During cellular mitosis, microtubules are essential for chromosome alignment and separation. **B.** Vincristine, one of the vinca alkaloids, attaches consistently to one end of the microtubule to inhibit microtubule assembly. **C.** Paclitaxel, one of the taxanes, binds to the inner ring of the microtubule and prohibits microtubule disassembly. In both B and C, microtubule function is impaired.

an emulsifying agent. Typically, the reaction develops within minutes of starting an initial infusion. Fortunately, the incidence can be decreased tenfold by premedication with corticosteroids, usually dexamethasone, 20 mg orally 12 and 6 hours before paclitaxel infusion. Neurotoxicity is the principal nonhematologic dose-limiting side effect. Common symptoms include numbness, tingling, and/or burning pain in a stocking-glove distribution. Peripheral neuropathy progresses with increased paclitaxel exposure and may become debilitating. Alopecia affects almost all patients and results in total body hair loss.

Docetaxel. This taxane is not FDA approved for gynecologic cancers but is often used to treat uterine sarcoma and occasionally recurrent epithelial ovarian cancer (Gockley, 2014; Herzog, 2014). In addition, patients with worsening peripheral neuropathy with paclitaxel are often switched to docetaxel, which has less neurotoxicity.

The usual dosage of docetaxel (Taxotere) is 75 to 100 mg/m^2 IV, repeated every 3 weeks. For recurrent ovarian cancer, weekly docetaxel is also effective at a dosage of 35 mg/m^2 IV for 3 consecutive weeks on a 28-day schedule (Tinker, 2007).

Myelosuppression is the main dose-limiting side effect. Fluid retention syndrome develops in approximately half of patients and manifests as weight gain, peripheral edema, pleural effusion, and ascites. Corticosteroid prophylaxis prevents most

TABLE 27-7. Chemotherapeutic Plant Alkaloids Used for Gynecologic Cancer

Generic Name	Brand Name	Indications	Routes	Dosages	Toxicity
Paclitaxel	Taxol	Recurrent epithelial ovarian CA, endometrial CA, cervical CA, GTN	IV, IP	IV: 135–175 mg/m^2 every 3 wk, or 80 mg/m^2/wk for 3 weeks IP: 60 mg/m^2 on day 8 following a day-1 IV dose	HSR, peripheral neurotoxicity, BMD, alopecia, bradycardia and arrhythmia
Docetaxel	Taxotere	Recurrent epithelial ovarian CA, uterine sarcoma	IV	75–100 mg/m^2 every 3 weeks, or 35 mg/m^2/week for 3 weeks	BMD, peripheral edema, HSR, alopecia
Vincristine	Oncovin	GTN	IV	0.8–1.0 mg/m^2 every other week	Neurotoxicity, abdominal pain, alopecia
Topotecan	Hycamtin	Recurrent epithelial ovarian CA, cervical CA	IV	1.5 mg/m^2/d, days 1–5, every 3 wk, or 4 mg/m^2/wk for 3 wk, or 0.75 mg/m^2/d, days 1–3, every 3 wk	BMD, N/V, alopecia, fever, malaise
Etoposide	VP-16	Germ cell or SCST ovarian CA; recurrent epithelial ovarian CA	IV, PO	IV: 100 mg/m^2 days 1 & 2, every 2 wk, or 75–100 mg/m^2, days 1–5, every 3 wk PO: 50 mg/m^2/day for 3 wk	BMD, alopecia, secondary cancers

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; HSR = hypersensitivity reaction; HTN = hypertension; IV = intravenous; N/V = nausea and vomiting; PO = orally; SCST = sex cord-stromal tumor.

of this toxicity, as well as dermatologic side effects and hypersensitivity reactions.

Vinca Alkaloids

Vincristine, vinblastine, and vinorelbine are cell cycle–specific drugs derived from the periwinkle plant with maximal activity in the M phase. These compounds inhibit normal microtubular polymerization by binding to the tubulin subunit at a site distinct from the taxane-binding site (see Fig. 27-4). These drugs are rarely used in gynecologic oncology. That said, vincristine is the "O" of EMA-CO combination chemotherapy for GTN treatment. The usual dosage of vincristine (Oncovin) is 0.8 to 1.0 mg/m^2 given IV every other week. The total individual dose is capped at 2 mg to prevent or delay neurotoxicity. This is the most common dose-limiting toxicity and may include peripheral neuropathy, autonomic nervous system dysfunction, cranial nerve palsies, ataxia, or seizures. Moreover, concurrent administration with other neurotoxic agents such as cisplatin and paclitaxel may increase severity. GI toxicity also is common, including constipation, abdominal pain, and paralytic ileus. However, myelosuppression is typically mild.

Topoisomerase Inhibitors

Topoisomerase (TOPO) enzymes unwind and rewind DNA to aid DNA replication. Topoisomerase inhibitors interfere with this function and halt DNA synthesis. This group is further divided into categories based on the specific topoisomerase enzyme they inhibit.

Topotecan. This TOPO I inhibitor binds to and stabilizes a transient TOPO I–DNA complex. This results in double-strand breakage and lethal DNA damage. Topotecan (Hycamtin) is FDA approved as salvage therapy of recurrent epithelial ovarian cancer and recurrent cervical cancer. It is infrequently used due to alternatives with fewer side effects (Long, 2005).

Topotecan is usually administered IV in two different schedules for recurrent ovarian cancer (see Table 27-7). When combined with cisplatin for recurrent cervical cancer, the usual dosage is 0.75 mg/m^2 on days 1 through 3, given every 3 weeks (Long, 2005).

Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect. GI toxicity also is frequent and includes nausea, vomiting, diarrhea, and abdominal pain. Systemic symptoms such as headache, fever, malaise, arthralgias, and myalgias are typical. Alopecia is often as complete as that seen with paclitaxel.

Etoposide. This cell cycle–specific agent has maximal activity in the late S and G_2 phase. Etoposide "poisons" the TOPO II enzyme by stabilizing an otherwise transient form of the TOPO II–DNA complex. As a result, DNA cannot unwind, and double-strand DNA breaks form. This agent is not FDA approved for gynecologic cancers. However, it is most often used IV as part of combination chemotherapy. Etoposide (VP-16) represents the "E" of the EMA-CO regimen, which is used for GTN. In addition, it is a component of the BEP regimen, used for ovarian germ cell or sex cord–stromal tumors. Oral etoposide

may be efficacious as a single agent for salvage treatment of recurrent epithelial ovarian cancer.

The dosage of etoposide varies. In the EMA-CO regimen, 100 mg/m^2 is administered IV on days 1 and 2, every 2 weeks. In the BEP regimen, it is usually prescribed in dosages of 75 to 100 mg/m^2 IV on days 1 through 5, given every 3 weeks. The oral dosage is 50 mg/m^2/day for 3 weeks, followed by a week off during a 28-day schedule.

Up to 95 percent of etoposide is protein-bound, mainly to albumin. Thus, decreased albumin levels result in a higher fraction of free drug and potentially a higher incidence of toxicity. Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect. GI symptoms of nausea, vomiting, and anorexia are usually minor, except with oral administration. Most patients will develop alopecia. With etoposide, particularly if the total dose exceeds 2000 mg/m^2, a later secondary malignancy is a small (approximately 1 in 1000) but significant risk. Acute myelogenous leukemia is the most common secondary cancer.

Miscellaneous

Carboplatin

Several antineoplastic compounds do not clearly fit into any of the preceding categories but have similarities with alkylating agents. Among these cell cycle–nonspecific drugs are carboplatin and cisplatin.

Carboplatin (Paraplatin) produces DNA adducts that inhibit DNA synthesis. This agent is one of the most widely used, particularly in adjuvant or salvage treatment of epithelial ovarian cancer, and is FDA approved for this indication. It is also frequently used off-label for endometrial cancer.

The usual IV dose of carboplatin is calculated to a target "area under the curve" (AUC) of 6, based on the glomerular filtration rate (GFR). For dose calculation, the Calvert equation is the most often used (Carboplatin total dose [mg] = AUC × [GFR + 25]). In clinical practice, the estimated creatinine clearance (CrCl) is usually substituted for the GFR and may be calculated by the Cockcroft-Gault equation (CrCl = [140 – age] × weight [kg]/0.72 × serum creatinine level [mg/100 mL]). The infusion takes 30 to 60 minutes, and dosing is repeated every 3 to 4 weeks.

Myelosuppression, most commonly thrombocytopenia, is the main dose-limiting side effect. GI toxicity and peripheral neuropathy are notably less severe than with cisplatin. Hypersensitivity reactions will eventually develop in up to 25 percent of women receiving more than six cycles.

Cisplatin

Similar to carboplatin, this agent produces DNA adducts that inhibit DNA synthesis. Cisplatin is one of the oldest and most widely used agents and is FDA approved for ovarian, cervical, and germ cell cancer. It may be given concomitantly with radiation as a radiosensitizing agent for primary treatment of cervical cancer or given as a single agent or in combination for recurrent cervical cancer. Alternatively, cisplatin is part of combination chemotherapy as the "P" of BEP, given for ovarian germ cell or sex cord–stromal tumors. However, for use in epithelial ovarian cancer, cisplatin has largely been replaced by carboplatin.

The usual dosage of cisplatin varies depending on the indication. In cervical cancer, dosages of 40 mg/m^2 IV weekly or 75 mg/m^2 every 3 weeks are given during radiation therapy. For patients with recurrent cervical disease, 50 mg/m^2 IV is provided every 3 weeks (Long, 2005). As part of the BEP protocol, cisplatin is administered 20 mg/m^2 IV on days 1 through 5 every 3 weeks. Alternatively, for ovarian cancer IP chemotherapy, cisplatin is given on day 1 or 2 of a 21-day cycle at a dose of 75 to 100 mg/m^2 (Armstrong, 2006; Dizon, 2011).

Cisplatin has several significant toxicities. Of these, nephrotoxicity is the main dose-limiting side effect. Accordingly, patients must be aggressively hydrated before, during, and after drug administration. Mannitol (10 g) or furosemide (20 to 40 mg) may be necessary to maintain a urine output of at least 100 to 150 mL/hour. With cisplatin, electrolyte abnormalities, such as hypomagnesemia and hypokalemia, are common. In addition, severe, prolonged nausea and vomiting can be dramatic without adequate premedication (Table 27-8). Patients often describe a metallic taste and loss of appetite following treatment. Neurotoxicity, usually in the form of peripheral neuropathy, can also be dose limiting and irreversible. Ototoxicity typically manifests as high-frequency hearing loss and tinnitus. Similar to carboplatin, hypersensitivity reactions may develop with prolonged use. Overall, cisplatin is significantly more toxic than carboplatin, except for its reduced hematologic toxicity.

Hormonal Agents

Tamoxifen

Due to their minimal toxicity and reasonable activity, hormonal agents are often used for palliative treatment of endometrial and ovarian cancers despite lacking formal FDA approval for these indications. Of these, tamoxifen is a selective estrogen-receptor modulator. It is a nonsteroidal prodrug and is metabolized into a high-affinity estrogen-receptor antagonist in breast tissue. It does not activate the estrogen receptor and thereby blocks breast cancer cell growth. The complex is then transported into the tumor cell nucleus, where it binds to DNA and halts cellular growth and proliferation in the G_0 or G_1 phase. Antiangiogenic effects also have been suggested. In addition to breast cancer, tamoxifen (Nolvadex) is occasionally used to treat endometrial and ovarian cancer (Fiorica, 2004; Hurteau, 2010).

Tamoxifen is orally administered and usually prescribed in doses of 20 to 40 mg for continuous daily use. Toxicity associated with tamoxifen is minimal, mainly consisting of menopausal symptoms. Moreover, some degree of fluid retention and peripheral edema develops in one third of patients. Reduced cognition and libido also may be noted during therapy.

In the endometrium, tamoxifen acts as a partial estrogen-receptor agonist. Sustained use increases the risk for endometrial polyp formation, and endometrial cancer risks triple. Moreover, thromboembolic event risks are raised, especially during and immediately after major surgery or periods of immobility. In contrast, tamoxifen prevents osteoporosis due to its partial agonist properties in bone and has beneficial effects on the serum lipid profile.

TABLE 27-8. Dose and Schedule of Antiemetics to Prevent Emesis Induced by Antineoplastic Therapy of High Emetic Risk

Antiemetics	Brand Name	Single Dose Administered before Chemotherapy	Single Dose Administered Daily
5-HT_3 serotonin-receptor antagonists			
Granisetron	Kytril	Oral: 2 mg IV: 1 mg or 0.01 mg/kg Transdermal patch: apply 1	
Ondansetron	Zofran	Oral: 8 mg twice daily IV: 8 mg or 0.15 mg/kg	
Palonosetron	Aloxi	IV: 0.50 or 0.25 mg	
Dolasetron	Anzemet	Oral: 100 mg	
Dexamethasone	Decadron	Oral: 12 mg	Oral: 8 mg, days 2–4
NK_1 receptor antagonist			
Aprepitant	Emend	Oral: 125 mg	Oral: 80 mg, days 2 and 3
Fosaprepitant	Emend	IV: 150 mg	
Olanzapine	Zyprexa	Oral: 10 mg	Oral: 10 mg, days 2–4

5-HT_3 = 5-Hydroxytryptamine-3; IV = intravenous; NK_1 = neurokinin 1.
From Hesketh, 2008, 2017.

Megestrol Acetate

This agent is a synthetic derivative of progesterone and has activity on tumors through its antiestrogenic effects. As such, megestrol acetate (Megace) is most often used to treat endometrial intraepithelial neoplasia (EIN), nonoperable endometrial cancer, and recurrent endometrial cancer, especially in those patients with grade 1 disease (Chap. 33, p. 716).

For cancer, the usual dosage is 80 mg twice daily. Megestrol acetate has minimal toxicity, but patients often gain weight from a combination of fluid retention and increased appetite. Thromboembolic events are rare. Patients with diabetes mellitus are carefully monitored because of the possibility of exacerbating hyperglycemia due to its concurrent glucocorticoid activity.

BIOLOGICAL AND TARGETED THERAPY

Differing molecular features within normal and malignant cells have led to targeted agents that exploit these differences. These advances, paired with an FDA initiative to accelerate approval, have revolutionized the availability of novel biologic agents. As a group, these targeted therapies offer the potential for improved long-term disease control with less toxicity.

Antiangiogenesis Agents

Angiogenesis is a normal physiologic process that forms new blood vessels and remodels vasculature for oxygen and nutrient transport to tissues. This process is usually transient and tightly regulated by various pro- and antiangiogenic factors. However, the homeostatic balance is dysregulated in malignancy. In cancers, sustained angiogenesis leads to tumor growth and metastasis and provides access to systemic lymphatic and circulatory systems. Thus, targeted inhibition of angiogenesis is an appealing therapeutic approach.

The binding of vascular endothelial growth factor (VEGF) to the VEGF receptor is a vital first step in stimulating normal angiogenesis. Many malignancies, such as ovarian cancer, are characterized by increased levels of VEGF or other proangiogenic factors. Several novel agents interfere with this process to halt tumor growth.

Bevacizumab

This agent is a monoclonal antibody that binds to VEGF to prevent VEGF interaction with its receptor (Fig. 27-5A). Currently, bevacizumab (Avastin) is FDA approved for persistent, recurrent, or metastatic cervical cancer. For advanced epithelial ovarian cancer, bevacizumab is coupled with chemotherapy after initial surgery and then used as single-agent maintenance. Last, it is suitable for relapsed platinum-resistant epithelial ovarian

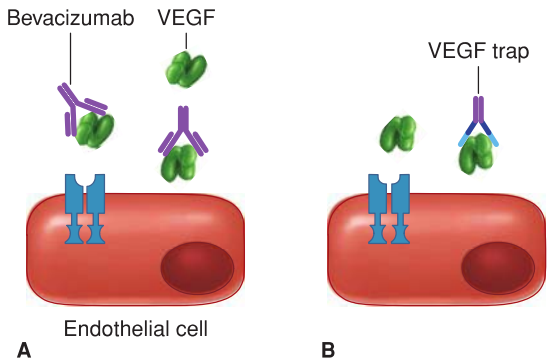

FIGURE 27-5 Mechanisms of action for two antiangiogenesis agents. **A.** Bevacizumab is a monoclonal antibody that binds vascular endothelial growth factor (VEGF). Binding prevents VEGF from combining with its endothelial-bound receptor, which is a receptor tyrosine kinase. **B.** VEGF Trap similarly binds VEGF and prevents receptor binding. In both cases, angiogenesis is inhibited, and tumor growth is halted.

cancer (Burger, 2011; Pujade-Lauraine, 2014; Tewari, 2014). Its usual dosage is 15 mg/kg given IV every 3 weeks with or without cytotoxic chemotherapy. In most cases, toxicity with bevacizumab is minimal. However, GI perforation may occur in up to 10 percent of patients (Cannistra, 2007). This complication is more likely in women with preexisting inflammatory bowel disease or in those with bowel resection at their primary surgery for advanced ovarian cancer (Burger, 2014). Elevated blood pressure is common and may lead to hypertensive crisis. Other possible toxicities include incomplete wound healing, weakness, pain, nosebleed, and proteinuria.

VEGF Trap

VEGF-A is the main isoform of VEGF. It can be bound by bevacizumab, as just described, or by a recombinant "fusion protein" named VEGF Trap (aflibercept). VEGF Trap is constructed by fusing two specific portions of the VEGF receptor and the "Fc" constant region of the IgG molecule. The receptor portions provide high-affinity binding of VEGF (see Fig. 27-5B). Clinical experience in gynecologic cancers is preliminary. Early reports suggest a risk of GI perforation similar to that for bevacizumab (Tew, 2014).

Cediranib

A receptor tyrosine kinase (RTK) inhibitor of VEGF, cediranib (Recentin), has demonstrated clinical activity in ovarian and cervical cancer. Even more promising results have been observed when this agent is combined with olaparib, a poly(adenosine diphosphate [ADP]) ribose polymerase inhibitor described later (Liu, 2014). Yet, significant toxicity that includes diarrhea and hypertension has limited more widespread drug development.

Lenvatinib

This oral agent is a multiple kinase inhibitor against all three isotypes of vascular endothelial growth factor receptor (VEGFR) and against other specific growth factor receptors. Lenvatinib (Lenvima) is FDA approved at a dose of 24 mg daily when used with pembrolizumab at 200 mg IV every 3 weeks for the treatment of advanced endometrial cancer. Hypertension occurs in one third of patients. Diarrhea, fatigue, and PPE also are reported (Makker, 2018).

Poly(ADP) Ribose Polymerase Inhibitors

A very promising group of targeted therapies, poly(ADP) ribose polymerase (PARP) inhibitors, exploit the differences in DNA damage repair between normal and malignant cells. During the cell cycle, DNA is routinely damaged thousands of times. Homologous recombination (HR) is an important pathway that repairs double-strand breaks, and PARP repairs single-strand breaks. In the functioning cell, if HR does not repair the break, PARP will (Fig. 27-6).

Until recently, HR was thought to be performed almost exclusively by the *BRCA1* and *BRCA2* genes. In fact, although up to one quarter of women with ovarian cancer have a predisposing germline mutation that is usually in *BRCA1* or *BRCA2*, numerous other HR deficiency genes (e.g., *BRIP1*, *RAD51C*) also may predispose cells to loss of repair function. Moreover, an additional 5 to 7 percent of patients develop somatic (acquired) HR mutations within the tumor that also result in similar repair dysfunction. In sum, half of all high-grade serous ovarian cancers have aberrations in HR repair (Pardoll, 2012). Normal cells do not replicate their DNA as often as cancer cells. And, without a mutation in one of the HR deficiency genes, they still have functional HR, which allows them to survive PARP inhibition. Thus, only tumor cells with nonfunctioning HR are almost entirely dependent on PARP repair. If PARP repair is prevented, cancer cell DNA cannot be repaired and cells die. In contrast, normal cells are unaffected.

Because most epithelial ovarian cancers have some degree of HR deficiency, even in patients without a confirmed *BRCA1* or *BRCA2* germline mutation, PARP inhibitors have become increasingly popular. All three clinically available PARP inhibitors are now FDA approved for maintenance treatment of

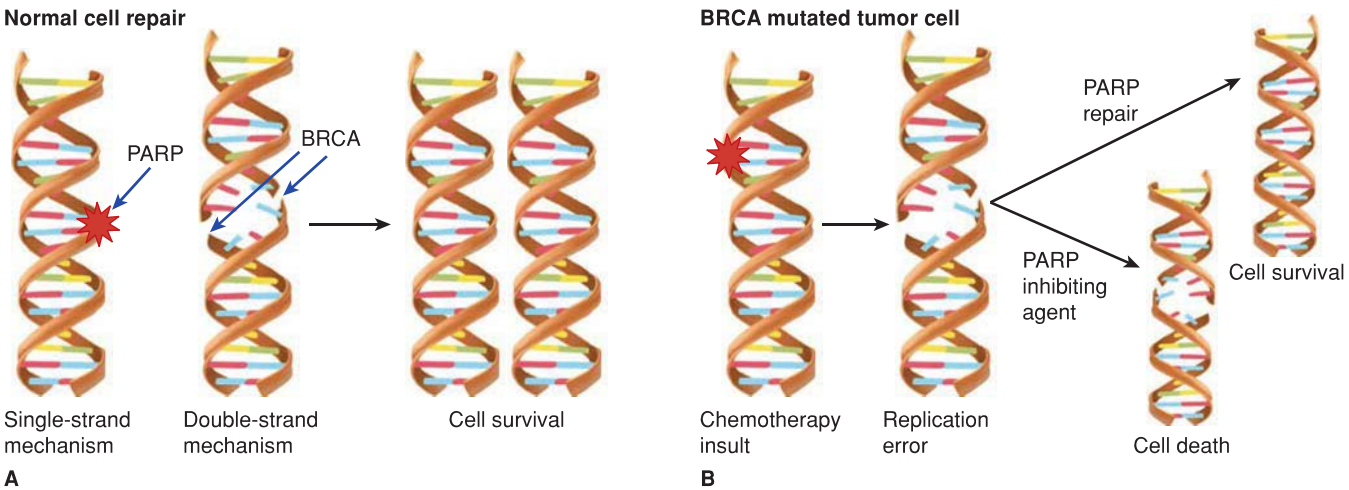

FIGURE 27-6 A. For DNA breaks, both PARP and homologous recombination (HR) pathways are important for repair and cell survival. HR is often but not exclusively performed by BRCA. **B.** With BRCA and other HR mutations, only PARP is available for DNA repair to permit cell survival. If a PARP inhibitor is administered, then DNA breaks are not repaired, and the tumor cell dies.

recurrent epithelial ovarian cancer following a complete or partial response to platinum-based chemotherapy. All three prolong survival, regardless of HR deficiency gene status, yet allow suitable quality of life during therapy (Coleman, 2017; Friedlander, 2018; Ison, 2018; Pujade-Lauraine, 2017).

Olaparib is used for *BRCA1* and *BRCA2* mutation carriers with relapsed ovarian cancer that has demonstrated resistance to platinum drugs (Kaufman, 2015). As a single agent, the usual oral dose is 300 mg twice daily. The most frequent toxicity is anemia, but other side effects are fatigue, nausea, or abdominal pain (Kaufman, 2015; Pujade-Lauraine, 2017).

Niraparib has a daily oral dose of 300 mg daily. Most significant side effects are hematologic and can be managed with dose adjustments (Mirza, 2016; Oza, 2018).

Rucaparib is used for patients with a *BRCA* mutation (germline or somatic) and with recurrent epithelial ovarian cancer treated by two or more courses of therapy. The oral dose is 600 mg twice daily. Side effects are few and include anemia, asymptomatic transaminitis, and bowel obstruction (Coleman, 2017; Swisher, 2017).

Immunotherapy

Another promising group of new drugs exploit the fact that cancer cells often have surface molecules, called tumor-associated antigens (TAAs), which can be detected by the body's immune system. Active immunotherapy targets TAAs, and directs the immune system to attack these tumor cells. In contrast, passive immunotherapies enhance existing antitumor responses by using monoclonal antibodies, lymphocytes, and cytokines.

Of passive immunotherapy agents, pembrolizumab (Keytruda) is the first cancer drug to be FDA approved based on tumor genetics rather than the tumor's tissue type or site of origin. Thus, it requires tumor profiling results before clinical use. Pembrolizumab is a therapeutic humanized antibody that targets and blocks the programmed cell death 1 (PD-1) receptor of T cell lymphocytes (Fig. 27-7). This receptor is an "immune checkpoint," responsible for preventing the immune system from attacking the body's own tissues. However, when a T cell's PD-1 receptor binds with the programmed cell death ligand (PD-L) on a tumor cell, it permits an attack by that lymphocyte. Cancers with microsatellite instability–high state (MSI-H) or DNA mismatch repair (MMR) deficiencies generate many mutated TAAs that bind to PD-1 and prohibit binding with the PD-L. This binding of TAAs and PD-1 thereby shuts down the ability of the host to kill the tumor on its own. By inhibiting PD-1 with pembrolizumab, the immune system is able to target and destroy these otherwise undetectable cancer cells. Yet, this same mechanism also allows the immune system to attack the body itself, and checkpoint inhibitors have immune-dysfunction side effects as a result (Pardoll, 2012).

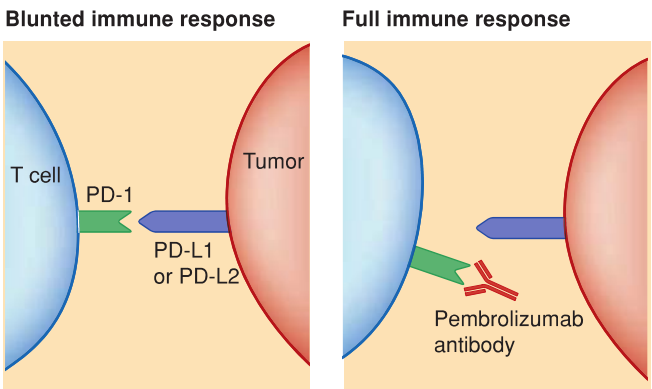

FIGURE 27-7 **A.** Normally, T cells recognize foreign peptides presented on cell surfaces. This recognition leads to a robust immune response. During this response, programmed cell death protein 1 (PD-1) limits T cell activity when it interacts with one of two ligands (PD-L1 or PD-L2). **B.** Action of the drug pembrolizumab. This agent is an antibody that binds to the PD-1 receptor and blocks its interaction with PD-L1 or PD-L2. This helps restore a robust immune response against a cancer cell.

Pembrolizumab is approved for any unresectable or metastatic solid tumor with MSI-H or MMR deficiencies and for advanced cervical cancer in PD-L1–positive patients (Frenel, 2017). In combination with lenvatinib, it is also FDA approved for advanced endometrial cancer (Makker, 2018). The dose of pembrolizumab is 200 mg IV every three weeks. In PD-L1–positive advanced cervical cancer, the response rate approximates 15 percent. Side effects are few and include rash and fever (Chung, 2018; Frenel, 2017).

Mammalian Target of Rapamycin Inhibitors

The *mammalian target of rapamycin (mTOR)* is a protein kinase that regulates membrane trafficking, transcription, translation, and cell cytoskeleton maintenance. Its downstream effect is to raise VEGF production. Thus, efforts to inhibit mTOR signaling also can inhibit angiogenesis. Rapamycin inhibits mTOR, and analogues of this drug, such as temsirolimus and everolimus, are currently being studied for gynecologic cancer treatment (Alvarez, 2013; Fleming, 2014; Slomovitz, 2010).

SIDE EFFECTS

Chemotherapy regimens, especially those including cytotoxic drugs, are universally toxic and display a narrow margin of safety. The Cancer Therapy Evaluation Program (CTEP) of the National Cancer Institute (NCI) has developed a detailed and comprehensive set of guidelines for the description and grading of toxicity. Termed the Common Terminology Criteria for Adverse Events (CTCAE), the most recent revision is version 5.0 and is available at http://evs.nci.nih.gov/ftp1/CTCAE/About.html.

In general, treatment modifications depend on the degree (grade) and duration of toxicity experienced. Doses are reduced if a woman experiences a severe reaction but then may be subsequently increased if tolerance improves. However, treatment is not resumed until toxicity has resolved to baseline or "Grade 1" levels and may be delayed on a week-to-week basis to permit recovery. Dose modification and supportive care are implemented to prevent delays of greater than 2 weeks, which would otherwise compromise therapeutic efficacy. Serious myelosuppression can be partially corrected

with the use of hematopoietic growth factors (p. 603). Many of the common toxicities can be prevented with proper use of premedications or alleviated with supportive measures.

Bone Marrow Toxicity

Myelosuppression, especially neutropenia, is the most common dose-limiting side effect of cytotoxic drugs. The absolute neutrophil count (ANC) is the critical measure when determining patient infection risk and may reflect mild (1000–1500/mm^3), moderate (500–1000/mm^3), or severe (<500/mm^3) neutropenia. Frequently, patients receiving therapy will have a nadir into the neutropenic range that will recover before the next scheduled treatment course. However, if they are admitted to the hospital for fever or other condition, neutropenic precautions should be observed. Although guidelines vary, these precautions include assiduous provider hand washing; provider outer gowns, gloves, and masks; and patient isolation from potential infection carriers.

Moderate degrees of anemia often develop in cancer patients receiving chemotherapy and may contribute to chronic fatigue. Frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. Synthetic erythropoietin is infrequently indicated and is discussed later (p. 603).

Thrombocytopenia is less common but may predispose the patient to serious bleeding if the platelet count drops below 10,000/mm^3. No predetermined platelet value should prompt routine transfusion, but ongoing bleeding in affected patients is a warranted indication.

Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. Typically, the emetogenic potential of a particular drug or regimen will dictate the antiemetic regimen used (Tables 27-9 and 27-10). Mild nausea and vomiting can often be managed effectively by prochlorperazine (Compazine) with or without dexamethasone. If drugs with more severe emetogenic effects such as cisplatin are administered, then ondansetron, granisetron, or palonosetron, which are 5-hydroxytryptamine antagonists, can be given IV before chemotherapy. Ondansetron (Zofran) and granisetron (Kytril)

TABLE 27-9. Emetic Risk of Intravenously Administered Antineoplastic Agents Used in Gynecologic Oncology

Emetic Risk	Incidence of Emesis (without Antiemetics)	Agent
High	>90%	Cisplatin Dactinomycin
Moderate	30–90%	Carboplatin Cyclophosphamide <1500 mg/m^2 Doxorubicin Ifosfamide
Low	10–30%	Etoposide Docetaxel Doxorubicin liposome Fluorouracil Gemcitabine Methotrexate Paclitaxel Temsirolimus Topotecan
Minimal	<10%	Bevacizumab Bleomycin Nivolumab Pembrolizumab Vinblastine Vincristine Vinorelbine

Items arranged alphabetically.

TABLE 27-10. Drug Regimens for the Prevention of Chemotherapy-Induced Emesis by Emetic Risk Category

Emetic Risk Category (Incidence of Emesis without Antiemetics)	Antiemetic Regimens and Schedules
High (>90%)	5-HT_3 serotonin receptor antagonist: day 1 NK_1 receptor antagonist: day 1 Olanzapine: days 1–4 Dexamethasone: days 1–4
Moderate (30% to 90%)	5-HT_3 serotonin receptor antagonist: day 1 Dexamethasone: days 1–3
Low (10% to 30%)	5-HT_3 serotonin receptor antagonist: day 1 *or* Dexamethasone: day 1
Minimal (<10%)	Prescribe as needed

5-HT_3 = 5-Hydroxytryptamine-3; NK_1 = neurokinin 1.
From Hesketh, 2008, 2017.

can also be provided orally to manage delayed and/or chronic nausea after chemotherapy. However, these drugs can induce significant constipation as a side effect. Chemotherapy-related diarrhea, oral mucositis, esophagitis, and gastroenteritis are treated with supportive care.

Dermatologic Toxicity

Drug-associated changes include hyperpigmentation, photosensitivity, nail abnormalities, rashes, urticaria, erythema, and alopecia. Many of these are drug specific and self-limited, but occasionally, they may be dose limiting. As discussed earlier, PPE is a known toxicity of liposomal doxorubicin (p. 595). In addition, changes in skin pigmentation are seen with bleomycin, whereas docetaxel can produce nail discoloration and onycholysis. Mild urticarial reactions are prevented or alleviated by premedication with diphenhydramine hydrochloride, 50 mg IV or orally.

One of the most emotionally distressing side effects of many chemotherapeutic agents is scalp alopecia. Fortunately, this is usually reversible. With some drugs such as paclitaxel, women will also experience loss of eyelashes, eyebrows, and other body hair. In general, techniques to minimize alopecia are unsuccessful. Instead, women are counseled regarding cosmetic options such as false eyelashes and wigs.

Neurotoxicity

Peripheral neuropathy develops commonly with cisplatin, paclitaxel, and the vinca alkaloids. Cisplatin-induced neurotoxicity usually resolves slowly, due to axonal demyelination and loss. To counter this toxicity, amifostine (Ethyol) may be administered, but substitution of carboplatin will avoid much of the toxicity. Gabapentin (Neurontin) is the usual treatment for neuropathic pain, starting at a dosage of 300 mg daily. Other options to treat symptomatic peripheral neuropathy that have shown some efficacy include oral glutamine (up to 15 g twice daily) or oral vitamin B_6 (up to 50 mg three times daily).

With chemotherapeutic agents in general, drug dosing may need to be adjusted if peripheral neuropathy becomes problematic—for example, if a patient can no longer hold a cup of coffee. More dramatic instances of acute cerebellar syndromes, cranial nerve palsies or paralysis, and occasionally acute and chronic encephalopathies are managed with supportive care and usually with discontinuation of the offending agent.

GROWTH FACTORS

Synthetic Erythropoietins

In some situations, hematopoietic drug factors to prompt red blood cell (RBC) or granulocyte production may have merit. Of these, epoetin alfa and darbepoetin alfa are synthetic erythropoietins that have the same biologic effects as endogenous erythropoietin to stimulate RBC production. These agents are recommended for patients with chemotherapy-associated anemia and a hemoglobin concentration that is approaching, or has fallen below, 10 g/dL. However, when used at higher hemoglobin levels, they may actually be associated with tumor progression and shorten survival (Rizzo, 2010). Moreover, several large studies have shown that despite reducing the need for RBC transfusions, erythropoiesis-stimulating agents (ESAs) increase the risk for thromboembolic events and death in cancer patients treated with epoetin alfa (Aapro, 2012; Tonia, 2012). As a result, the FDA issued a "black-box" warning stating that a higher mortality rate and/or shortened time to tumor progression were found when ESAs were dosed with the intent to achieve hemoglobin values ≥12 g/dL compared with placebo or observational controls. Once routinely used, these agents are now infrequently administered to gynecologic cancer patients due to safety concerns.

When used, epoetin alfa (Procrit, Eprex, and Epogen) is usually prescribed as 40,000 units SC weekly (Case, 2006). Beyond local pain at the injection site, this agent has minimal side effects. Possible toxicity may include diarrhea, nausea, or hypertension (Bohlius, 2006; Khuri, 2007). For darbepoetin alfa (Aranesp), the usual SC dose is 200 μg every other week or 500 μg given every 3 weeks. Darbepoetin alfa has minimal side effects beyond local pain at the injection site.

Granulocyte Colony-Stimulating Factors

Filgrastim and pegfilgrastim are human granulocyte colony-stimulating factors (G-CSF) produced by recombinant DNA technology. As such, these cytokines bind to hematopoietic cells and prompt proliferation, differentiation, and activation of granulocyte progenitor cells. These growth factors are mainly used to prevent episodes of febrile neutropenia (ANC <1500), particularly in patients with a greater than 20-percent risk for such an event. Fortunately, none of the common regimens used in the treatment of gynecologic cancer have a risk that exceeds 20 percent, and thus growth factors are typically not required for initial prophylaxis. Instead, growth factors are usually indicated following a neutropenic event and chemotherapy delay to permit a patient to maintain her treatment schedule.

Filgrastim (Neupogen) is given SC, and the usual SC dose is 5 μg/kg/d. However, patients typically are given either 300 μg or 480 μg, which is the content of manufactured vials. It should be administered at least 24 hours after chemotherapy completion. Therapy is terminated when the white blood count (WBC) exceeds 10,000/mm^3 or when the ANC exceeds 1000/mm^3 for 3 consecutive days. Toxicity with filgrastim is limited, and transient bone pain is usually mild to moderate.

Pegfilgrastim (Neulasta) acts similarly to filgrastim to stimulate production of granulocyte progenitor cells within the bone marrow. The "peg" in pegfilgrastim refers to a polyethylene glycol unit that prolongs the time it remains in the body. Pegfilgrastim is given as a single 6-mg SC injection once per chemotherapy cycle. This is usually far more convenient than daily filgrastim doses. It should not be administered during the 14 days before and within 24 hours after administration of cytotoxic chemotherapy. Transient bone pain is usually mild to moderate, but often more pronounced than with filgrastim.

TUMOR PROFILING

The ability to identify distinct molecular alterations by tumor profiling, so-called precision medicine, has led to more effective targeted treatment with biological agents. Currently, the FoundationFocus CDxBRCA test is an FDA-approved test detecting germline (inherited) and somatic (acquired) *BRCA1* and *BRCA2* gene mutations. With positive results, potential candidates for PARP inhibitor therapy are identified. To aid pembrolizumab therapy selection, the PD-L1 IHC 22C3 pharmDx test is FDA approved for cervical cancer patients. PD-L1 protein expression is significant when the Combined Positive Score (CPS) exceeds 1. The CPS is the number of PD-L1 staining cells divided by the total number of viable tumor cells, multiplied by 100.

Less rigorous chemotherapy sensitivity and resistance assays are theoretically appealing due to the possibility of tailoring treatment. Using this strategy, viable tumor tissue is collected from the patient during surgery or other intervention (e.g., paracentesis). The sample is shipped to a specialized laboratory. Here, in vitro analysis determines whether tumor growth is inhibited by a drug or panel of drugs.

The potential of selecting effective cancer treatments while sparing unnecessary ones is intriguing, and patients may even request testing. However, no current assay has demonstrated sufficient efficacy to support its use. Thus, these assays are not recommended for individual patients outside of a clinical trial (Burstein, 2011).

CANCER DRUG DEVELOPMENT

The only proven way to improve cancer treatment success rates is to test new agents, higher doses, novel combinations, or unique ways of administering treatment. Promising drugs are usually first identified by demonstrating success in cancer cell lines or in animals inoculated with tumor. After preclinical steps, novel agents traditionally proceed through four phases of clinical testing.

Phase I trials use a dose-escalating design to determine the dose-limiting toxicity, maximum tolerated dose (MTD), and pharmacokinetic parameters of the drug. In a Phase I trial, detecting a tumor response is not critical, since enrolled patients have typically completed extensive prior therapy. However, observed responses would encourage further disease-specific Phase II trials.

Phase II trials aim to define the actual response rate in patients with a specific cancer type. Typically, patients enrolled in Phase II trials have received only one prior chemotherapy regimen. This allows for a reasonable chance of response compared with subjects in Phase I studies. End points of Phase II trials include a measure of disease response, determination of the "progression-free interval," cumulative incidence of dose-limiting toxicity over multiple cycles, and overall survival rates.

Phase III randomized trials are designed to directly compare the drug with existing standard regimens in a particular stage and type of cancer. Phase III trials generally require a minimum of 150 patients per "arm" to provide adequate statistical precision. Finally, Phase IV clinical trials evaluate drugs that are already FDA approved. The goal of Phase IV trials is to study long-term drug safety and efficacy.

In general, although patients are strongly encouraged to participate in appropriate phase I, II, and III clinical trials, fewer than 5 percent do so. Doing so expands their options for treatment. In addition to expanding their options for treatment, the results of such studies are the primary method to improve the future outcomes of women diagnosed with gynecologic cancer.

REFERENCES 618

To effectively incorporate radiation treatment into cancer care, clinicians must understand the fundamental concepts and vocabulary used in radiation oncology. Clinically, radiation therapy, often combined with chemotherapy, can be used as primary treatment for many gynecologic malignancies (Table 28-1). Additionally, radiation therapy may be recommended postoperatively if the probability of tumor recurrence is high. Radiation therapy is also used frequently in the relief of symptoms caused by metastasis of any gynecologic cancer.

RADIATION PHYSICS

Radiation therapy is the focused delivery of energy in tissue to accomplish controlled biologic damage. Radiation used in this therapy can be delivered as electromagnetic waves or particles.

Electromagnetic Radiation

Photons (x-rays) and *gamma rays* are the two types of electromagnetic radiation used for radiation therapy. Photons, used in *external beam therapy*, are produced when a stream of electrons collides with a high-atomic-number target (tungsten) located in the head of a linear accelerator (Fig. 28-1). In contrast, gamma rays originate from unstable atom nuclei and are emitted during decay of radioactive materials, also termed *radionuclides*, which are widely used in *brachytherapy*.

TABLE 28-1. Role of Radiation Therapy in the Management of Gynecologic Cancers

Intent	Site
Curative	Cervix, vulva, vagina, uterus
Adjunctive to surgery	Cervix, vulva, vagina, uterus
Palliative	Metastasis causing symptoms: bleeding, pain, obstruction

Particle Radiation

Whereas electromagnetic waves are defined by their wavelengths, particles are defined by their masses. For clinical use, particles include electrons, neutrons, protons, helium ions, heavy charged ions, and pi mesons. Except for electrons, which are available in all modern radiation oncology centers, and protons, other particles have limited clinical use. Proton facility numbers are expanding, with 30 facilities operating in the United States and 14 additional centers planned or under construction.

Particles are produced by linear accelerators or other high-energy generators and are usually delivered by external beam. Of clinically used particles, *electrons* are negatively charged and deposit most of their energy near the surface. In contrast, heavy charged particles, such as *protons*, deposit most of their energy in the absorbing tissues as their velocity decreases, that is, near the end of the particle path (the Bragg peak effect). Because of this, a major advantage of proton therapy is the lack of an exiting dose through normal tissues. Proton therapy use for gynecologic malignancies is primarily investigational. But as an example, proton therapy can treat affected deep pelvic and paraaortic lymph nodes, while sparing unnecessary dosing and injury to anterolateral organs, such as the bowel and kidneys (Fig. 28-2).

Radiation Sources

Radionuclides

Also called *radioisotopes*, radionuclides undergo nuclear decay and can emit: (1) positively charged alpha particles, (2) negatively charged beta particles (electrons), and (3) gamma rays. Radionuclides commercially available are shown in Table 28-2. Cesium and iridium are commonly used in gynecologic brachytherapy.

Linear Accelerator

One of the main types of radiation-producing units is the linear accelerator, also called a *linac*. A linac can produce both photon and electron beams (see Fig. 28-1). In the *photon-therapy mode*, indicated for deep-seated tumors, the accelerated electron beam is guided to hit a metal target to produce photons. The unit

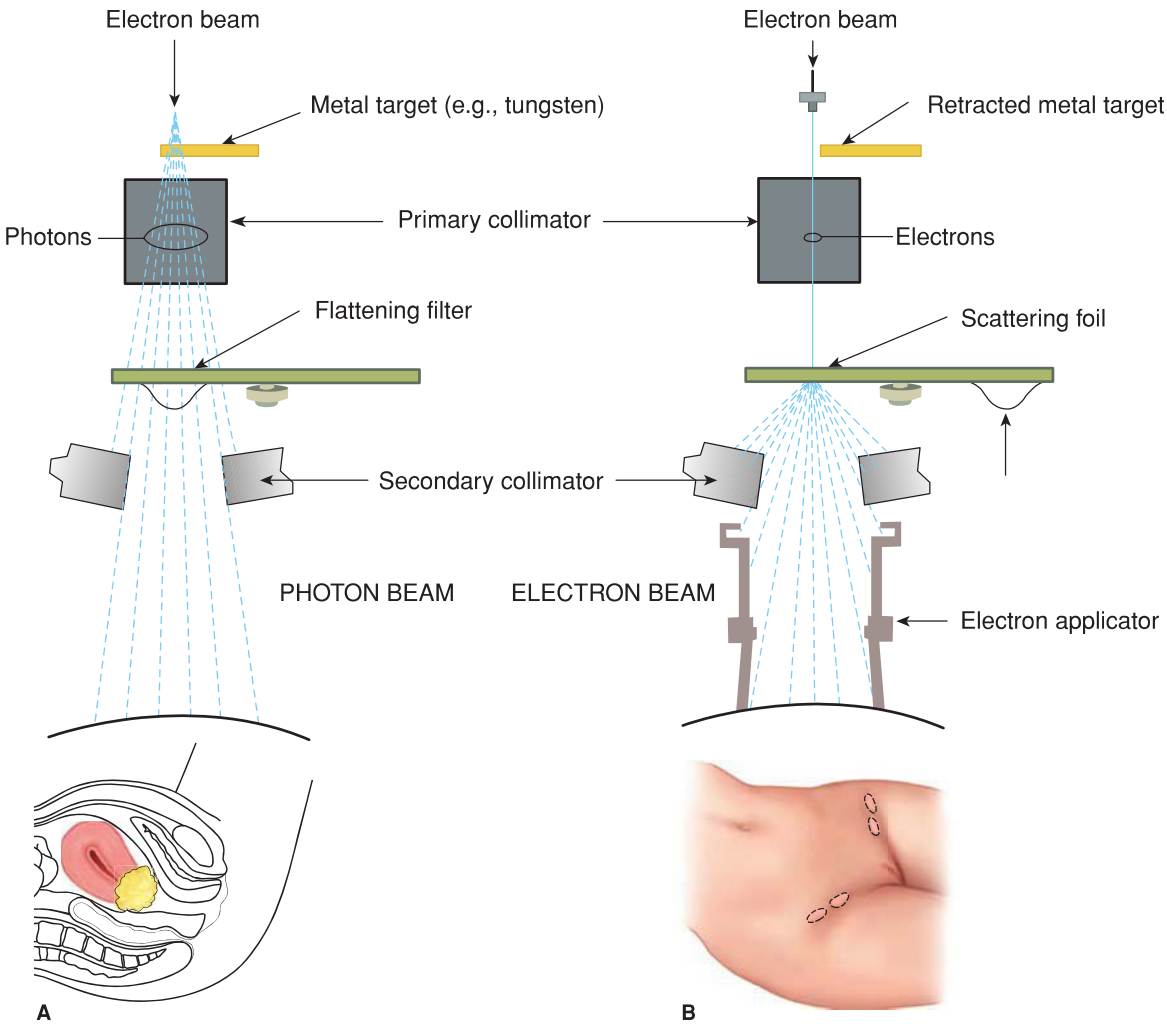

FIGURE 28-1 Block diagram of a linear accelerator used to create external beam radiation. Either photon beams or electron beams may be produced. **A.** Photon beam therapy is suited for deep tumors such as the cervical cancer shown here. Beam energy is measured in millions of volts (MV). **B.** Electron beam therapy is indicated for superficial lesions such as inguinal lymph nodes. Beam energy is measured in millions of electron volts (MeV).

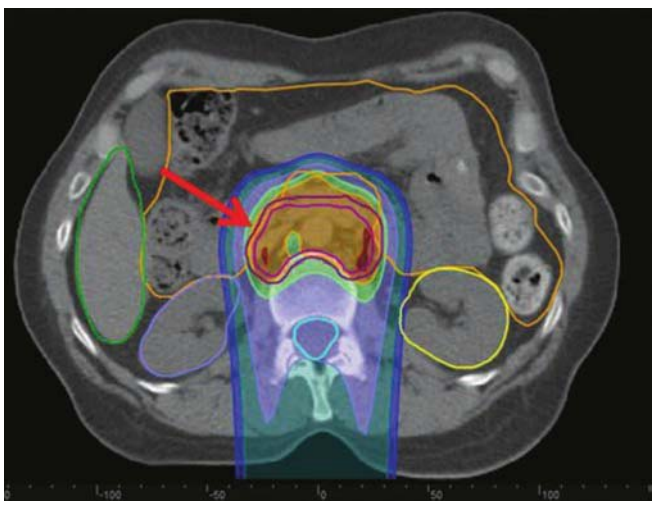

FIGURE 28-2 Proton dose distribution in a patient with cervical cancer receiving treatment to the paraaortic lymph nodes. The proton beam originates posteriorly and is directed anteriorly. The red arrow shows the target volume (*dark magenta*). The area anterior to this is bowel (*orange outline*), which is significantly spared from radiation.

used to describe the energy of a photon beam is MV (million volts). In the *electron-therapy mode,* indicated for superficial lesions, the electron beam strikes a lead scattering foil instead of the metal target. The unit for electron beam energy is MeV (million electron volts). Figure 28-3 displays a linac with three moveable components: gantry, treatment head, and couch. These components can all rotate 360 degrees, which allows multiple fields and angles to achieve optimal dose delivery to a tumor.

Electromagnetic Radiation Energy Deposition

When electromagnetic radiation is used in daily clinical practice, it contacts target tissues, and energy is transferred to those tissues. This transfer creates ions by dislodging electrons from atoms within these tissues. These electrons then collide with surrounding molecules to initiate radiation damage.

Three mechanisms are involved in energy transfer: (1) photoelectric effect, (2) Compton effect, and (3) pair production

TABLE 28-2. Physical Properties and Clinical Use of Selected Radionuclides

Element	Radiation Energy (MeV)	Half-Life	Clinical Use
Cesium-137	0.6	30 years	Brachytherapy
Iridium-192	0.4	74 days	Brachytherapy
Cobalt-60	1.2	5 years	Brachytherapy
Iodine-125	0.028	60 days	Brachytherapy
Phosphorus-32	1.7	14 days	Intraperitoneal instillation
Gold-196	0.4	2.7 days	Intraperitoneal instillation
Strontium-89	1.4	51 days	Diffuse bone metastases
Samarium-153	0.6	1.9 days	Diffuse bone metastases

MeV = million electron volts.

(Fig. 28-4). Depending on the energy level of the incident radiation, one of these mechanisms will predominate. The *photoelectric effect* is dominant if the incident energy is low (less than 100 kV). The *Compton effect* dominates in mid- to high energy ranges (1 MV to 20 MV) and is the most important in clinical radiation therapy. Last, *pair production* occurs when a photon beam with very high energy (beyond 20 MV) strikes the electromagnetic field of the nucleus.

Depth-Dose Curve

Controlled biologic damage is accomplished by greater selective radiation dose distribution within malignant tissue than within the surrounding, "innocent bystander" normal tissues. This is achieved by using radiation beams with differing physical properties to define the spatial distribution of an absorbed dose when these beams strike tissue. Ideally, an absorbed radiation dose is as conformal as possible. Perfect conformality is achieved when the targeted malignant tissue absorbs 100 percent of the prescribed dose and the adjacent normal tissues absorb 0 percent.

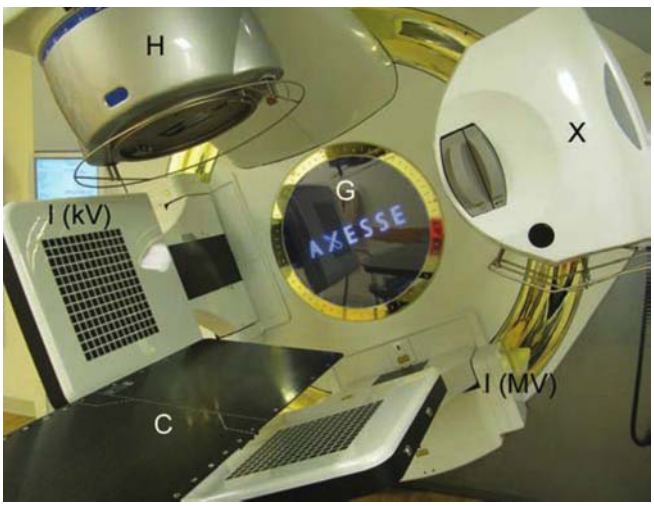

FIGURE 28-3 Linear accelerator currently in use at Tufts Medical Center. The patient lies on the treatment couch (C). The gantry (G), couch, and head (H) can all rotate and allow radiation beams to reach target tissues through different angles. A kV x-ray source (X) is used in conjunction with an image intensifier (I-kV) for image-guided radiotherapy (IGRT). Another image intensifier (I-MV) is used for standard port imaging.

In practice, this cannot be obtained. However, both acute radiation side effects and the potential for late, delayed radiation complications can be minimized as the spatial radiation dose distribution approaches this ideal.

A *depth-dose curve* specifically illustrates the dose distribution of a given radiation beam as it penetrates tissues. Radiation oncologists rely on these curves when choosing a radiation beam with an appropriate energy to reach a given tumor. With electron beam therapy, the maximum dose lies close to the surface, and therefore, electron beam therapy is indicated for targets that are close to the skin surface, such as metastatic cancer to the inguinal lymph nodes. With high-energy photons, the maximum dose is deposited well below the surface. Beyond this point, the dose gradually diminishes as energy is absorbed by the deep surrounding tissues. This explains the so-called *skin-sparing effect* of high-energy photons. A patient with a pelvic malignancy is usually treated with at least 6-MV photon beams.

Dosimetry

This is the discipline of calculating the radiation dose absorbed by the patient. Dosimetric calculations are based on the depth-dose measurements of the radiation beams used to treat an actual patient. The dose distribution is usually displayed as a colorful map overlaid on the radiologic images of the patient (see Fig. 28-2). These calculations *predict* the absorbed dose in a given situation.

Radiation Unit

Quantification of the absorbed radiation dose is essential, as it correlates with the biologic effect of radiation. The current Standard International unit for absorbed dose is gray (Gy). One Gy equals 100 rad or 1 joule/kg. Clinically, the radiation doses for curative and palliative treatment are 70 to 85 Gy and 30 to 40 Gy, respectively.

RADIATION BIOLOGY

DNA Molecule as Radiation Target

The DNA molecule is the target for the biologic effect of radiation on mammalian cells. DNA injuries involve its strands, bases, and cross-links, but the hallmark damage is breaking of single- and

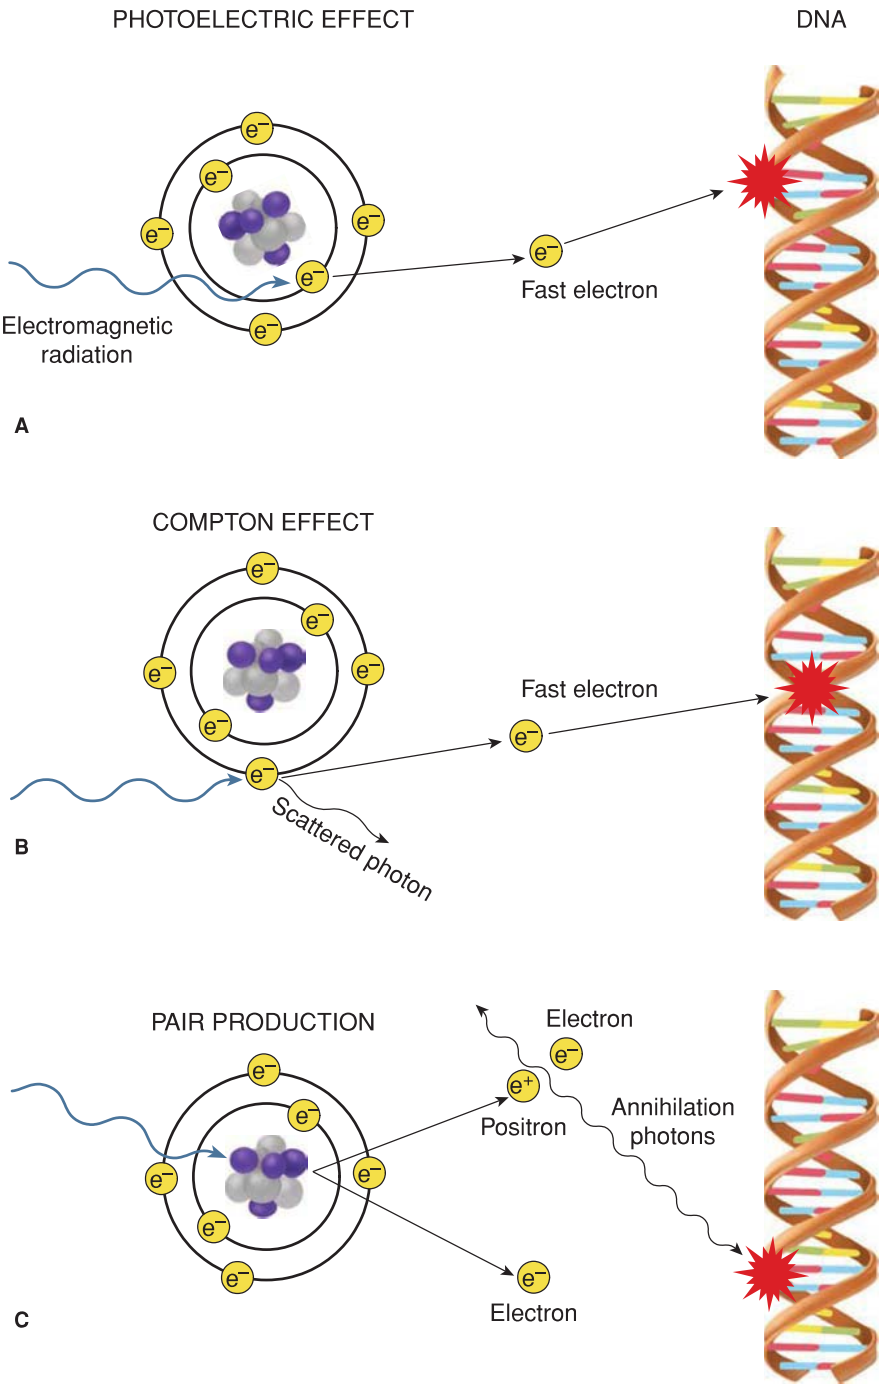

FIGURE 28-4 When electromagnetic radiation impacts target tissues, energy is transferred to those tissues. The three mechanisms involved in this energy transfer are the photoelectric effect, Compton effect, and pair production. Both photoelectric effect **(A)** and Compton effect **(B)** result in creation of fast electrons, which then initiate the biologic process of radiation damage. **A.** With photoelectric effect, radiation interacts with an inner orbital electron. **B.** With Compton effect, interaction occurs with an outer orbital electron. **C.** During pair production, impact of radiation on the atom's nuclear forces produces a positron-electron pair. When a positron later combines with a free electron in these tissues, two photons are created, which can then lead to radiation damage.

Direct versus Indirect Actions of Ionizing Radiation

Radiation can interact *directly* or *indirectly* with the atoms in the DNA molecule. Direct actions create ions that then initiate the biologic damage process. This *direct* effect is predominant with high linear energy transfer (LET) particles such as protons, fast neutrons, and heavy ions (Fig. 28-5). However, most DNA damage is caused indirectly, which is the predominant effect with low-LET particles such as photons. Indirect DNA damage occurs through an important chemical intermediate, the hydroxyl radical (·OH), which is highly reactive because of its unpaired electron.

Cell Death

The two main cell death pathways after radiation are *apoptosis* and *mitotic catastrophe*. Mitotic catastrophe is thought to be the most common mechanism of cell death after radiation exposure. With this, cells with damaged DNA enter mitosis prematurely, before DNA can be repaired, and die attempting to complete the next two to three mitotic cycles. Apoptosis, or programmed cell death, occurs after an intracellular stress, such as radiation-induced irreparable double-strand breaks. A series of events develop rapidly within hours, leading to cell membrane blebbing, apoptotic body formation in the cytoplasm, chromatin condensation, nuclear fragmentation, and DNA laddering (Okada, 2004).

Four R's of Radiation Biology: Repair, Reassortment, Repopulation, Reoxygenation

In classic radiation biology, cells respond to radiation by four mechanisms. Cellular *repair* can be described by sublethal damage repair (SLDR) and potentially lethal damage repair (PLDR). SLDR occurs when a radiation dose is split into two or more fractions and a few hours separate the fractions. Cells have time to repair their damage, and their survival rate increases. The last process seen in SLDR is *repopulation*, which is the tissue's response to replenish the cell pool (Trott, 1999).

Following the initial repair of sublethal damage, *reassortment* begins. Within a tumor, proliferating cells are in different phases of the cell cycle (Fig. 27-1, p. 581). Cells in mitosis (M) and G_2

most importantly double-stranded DNA. Double-strand breaks lead to DNA fragmentation when two or more breaks are formed and when cells attempt to repair these strand breaks. The DNA pieces may rejoin incorrectly, leading to gene translocation, mutation, or amplification, and ultimately cell death.

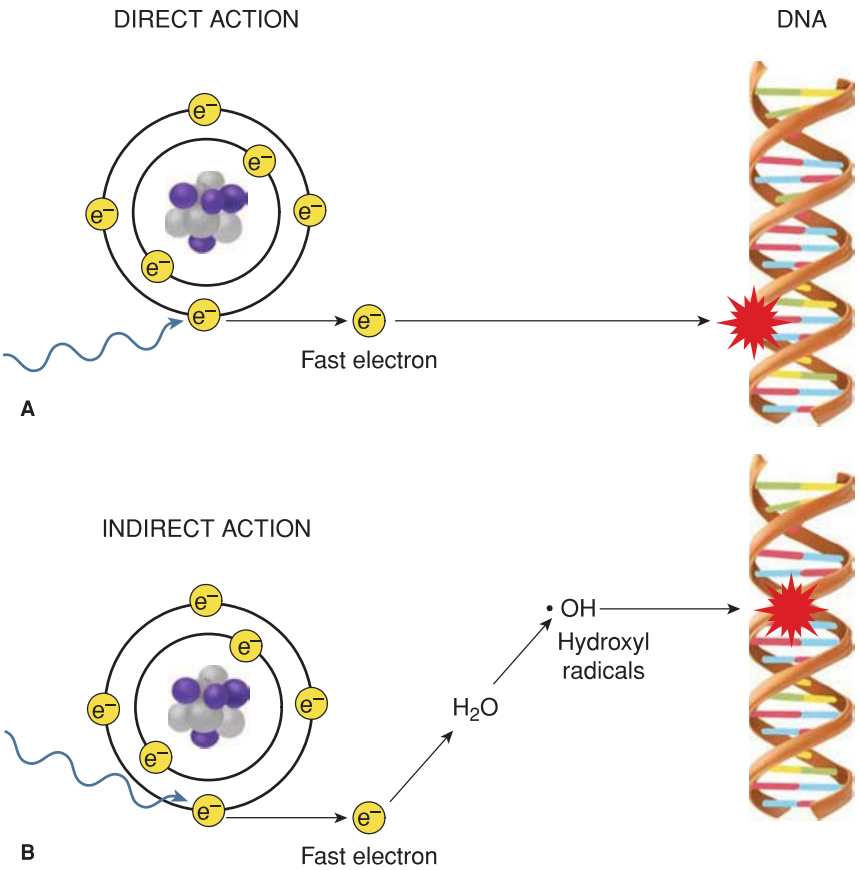

FIGURE 28-5 Direct and indirect actions of radiation. **A.** Fast electrons may directly strike DNA to create damage. **B.** Alternatively, a fast electron may interact with water to create a hydroxyl radical, which subsequently interacts with DNA to cause injury.

are most sensitive to radiation. Conversely, cells in G_1 and S (DNA synthesis) phases are less sensitive (Pawlik, 2004). When exposed to radiation, those cells that are in the G_2/M phase are killed. During reassortment, surviving cell populations restart their progression through the mitotic cycle.

The fourth "R" of radiation biology theory is *reoxygenation.* A tumor cell population is composed of oxygenated and hypoxic components. Cells located within 100 microns of blood capillaries are oxygenated, and beyond 100 microns, cells are hypoxic. After radiation, the oxygenated cells are killed by the hydroxyl radical described earlier. Following cell death, the tumor shrinks and allows hypoxic cells to be positioned within the oxygen diffusion range of blood capillaries. Thereby, they become oxygenated and susceptible.

Linear-Quadratic Theory and the Alpha/Beta Ratio

For low-LET radiation, the linear-quadratic curve has been adopted to explain the relationship between the fraction of cells surviving a given dose of radiation (Fig. 28-6). The initial linear (alpha) portion of the curve shows that the probability of cell death is proportional to the radiation dose. In the higher-dose region, the curved quadratic (beta) portion indicates that the probability of cell death is proportional to the *square* of the dose.

The alpha/beta ratio reflects the response of normal tissues to radiation. *Early-responding tissues* have a high alpha/beta ratio and will manifest reactions to radiation within a few days to weeks after treatment. Examples are tissues with high proliferation rates such as bone marrow, reproductive organs, and gastrointestinal tract mucosa. Preventatively, by administering multiple small radiation dose fractions, sublethal damage repair predominates, and early acute reactions can be decreased.

In contrast, *late-responding* tissues show clinical reactions only weeks to months after completion of a radiation therapy course. Examples are the lung, kidney, spinal cord, and brain. These tissues have a low alpha/beta ratio and are slow to respond. More time is needed to repair sublethal damage, and thus high-dose-per-fraction radiation therapy can easily lead to severe late complications.

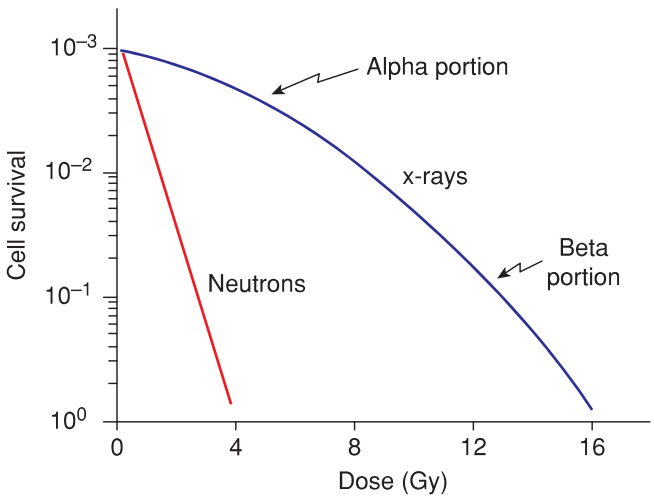

FIGURE 28-6 Linear quadratic mammalian cell survival curve. The cell survival is plotted on a logarithmic scale. The dose (in Gy) is on a linear scale. The typical cell survival curves with low-LET (linear energy transfer) (*blue curve*) and with high-LET radiation (*red line*) are shown. With low-LET x-ray doses, the alpha (linear) portion of the curve is flat and shows that cell survival is proportional to the dose. However, as the dose increases, the beta (quadratic) portion bends, which implies that cell survival is proportional to the dose squared. In contrast, with high-LET radiation, such as neutrons, the survival curve is straight.

RADIATION ONCOLOGY PRACTICE

The expertise of the radiation oncologist who is designing and monitoring a course of radiation treatment is paramount. The radiation oncologist carves out, en-bloc, a volume of cancerous tissue, its local extensions, and its regional lymphatics, while accommodating the patient's comorbidities, general health status, and surrounding normal tissue quality.

As cancer management is frequently multimodal, superior treatment outcomes are highly dependent on clear communication between radiation oncologists and their colleagues in surgical and medical oncology. Optimal integration of diagnostic imaging and histologic evaluation also is vital to planning and implementing potentially curative radiation therapy. As such, early involvement of the radiation oncologist in patient evaluation and counseling enhances the probability of effective and coordinated cancer care.

Radiation Fractionation Schemes

Parameters that affect the efficacy and safety of a radiation course include the total radiation dose applied, the size of each radiation "fraction" (treatment), the time between treatments ("fractionation schedule"), and the elapsed time to deliver the total prescribed dose.

Standard Fractionation

Successful eradication of a localized cancer requires that the cancer cells be killed more rapidly and efficiently than surviving cancer cells can proliferate and repopulate. Because of the inevitable exposure of some normal tissues to substantial radiation, limits are placed on the total radiation dose that can be prudently administered to a given target volume. In general, delivery of this dose over the shortest feasible elapsed time will maximize efficacy. Accomplishing this objective is limited by the known deleterious consequences of a high dose per fraction on normal tissues. As noted, this can result in delayed radiation injury expressed months or years after therapy completion. For this reason, radiation delivered with curative intent is generally administered in daily treatments (Monday through Friday) of 1.8 Gy to 2.0 Gy. Cumulative doses range from 45 Gy to treat microscopic disease to 70 Gy or more to treat gross disease. This concern for delayed injury is less when short courses of radiation are administered with palliative intent, often in dose fractions of 2.5 Gy to 4.0 Gy.

Altered Fractionation

Regimens involving treatments given more than once a day are reserved for selected cases. In such instances, increased local tumor control and decreased long-term complications may be achieved by manipulating both fraction size and overall treatment time. Two major strategies have been employed, namely, hyperfractionation and accelerated treatment.

With *hyperfractionation*, the goal is to reduce late damage to normal tissues, and accordingly, a smaller dose per fraction is given. Two or more fractions are administered each day, typically 6 hours apart to provide an interval for normal tissue repair.

Accelerated fractionation shortens the treatment duration with or without a drop in the total dose to overcome tumor cell repopulation. The usual weekend break is either shortened or eliminated. With accelerated treatment, however, severe acute reactions are frequent.

Altered fractionation has been studied in gynecologic cancers. Radiation Therapy Oncology Group (RTOG) trials 88-05 and 92-10 were Phase II trials that investigated the use of twice-daily radiation and chemoradiation, respectively, in advanced cervical cancer. RTOG 88-05 showed similar local control, survival rates, and toxicity compared with historical controls. However, when chemotherapy and larger-field twice-daily radiation were added, rates of late Grade 4 toxicity were unacceptably high (Grigsby, 2001, 2002).

Radiation Therapy

External Beam Radiation Therapy

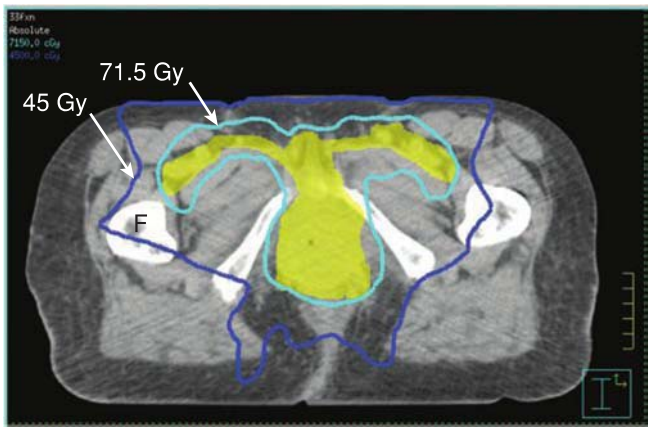
External beam radiation therapy is indicated when an area to be irradiated is large. For example, the fields needed to treat a locally advanced cervical cancer may cover the whole pelvis and, occasionally, the paraaortic lymph nodes.

Conformal radiation therapy (CRT) describes a radiation treatment technique that maximizes tumor damage yet minimizes injury to the surrounding normal tissues. To achieve this goal, the radiation oncologist must know the precise extent of the cancer to be irradiated and its relationship to surrounding normal tissues. This process begins with a review of the patient's cancer imaging including computed tomography (CT), magnetic resonance (MR) imaging, and positron emission tomography (PET). Imaging, along with careful review of the patient's pathology and operative report, assists in defining the 3-dimensional (3-D) target (tumor or regions of potential microscopic tumor spread) and normal tissue volumes.

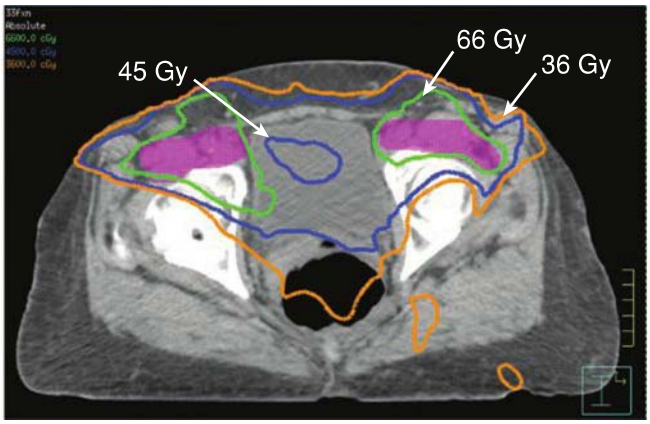
Next, a simulation is performed in a simulation suite to delineate the anticipated therapy fields prior to an actual treatment session. During this process, patient positioning, immobilization techniques, and treatment fields are defined. If feasible, radiation blocking techniques are used to shape the treatment beams to shield normal tissues. The patient is placed in the treatment position, and a CT scan of the area of interest is performed. Later, on each of the computer-based CT scan slices, the radiation oncologist carefully delineates the anatomic areas that will receive a tumoricidal dose. During this, four volumes are defined: (1) a gross tumor volume (GTV), which encompasses any gross disease; (2) a clinical target volume (CTV), which incorporates any areas at risk for microscopic tumor spread; (3) a planning target volume (PTV), which accounts for uncertainties in treatment delivery such as patient motion or daily set-up error; and (4) a volume that defines the normal organs at risk (OAR), which will be exposed, albeit to a lesser radiation dose.

Once simulation is completed, a radiation dosimetrist employs treatment planning software to develop an optimal plan, called *dose optimization*. This is often a reiterative process in which the physician and the dosimetrist will arrive at an acceptable option, which means an optimal arrangement and shaping of the radiation beams.

One tool that is particularly helpful during radiation planning and optimization is the dose-volume histogram (DVH). This is a graphic summary of the entire dose distribution to the cancer and normal structures. Thus, the DVH provides information regarding whether the cancer will be adequately treated with a tumoricidal dose and whether surrounding normal structures are minimally affected. In addition to the DVH, dose distributions are displayed as computer-generated radiation dose map images that are overlaid on the CT images. This provides a visual dose-anatomy relationship. These dose distributions are produced for



A



B

FIGURE 28-7 IMRT dose distribution in a patient with stage T4 N2 M0 cancer of the vulva. This technique allows for the delivery of tumoricidal doses to the vulva and inguinal nodes while minimizing that to normal tissues. **A.** The yellow area displays the actual vulvar cancer and inguinal lymph nodes. Doses to the vulva and femoral heads (F) are shown (*arrows*). The doses to the vulva and femoral heads are 71.5 Gy and 45 Gy, respectively. **B.** Pink shading displays the inguinal nodes. Doses to the inguinal nodes, bladder, and rectum are shown (*arrows*). The doses to the inguinal nodes, bladder, and rectum were 66 Gy, 45 Gy, and 36 Gy, respectively.

the radiation oncologist to review, adjust, and finally approve. The final chosen plan is reviewed by a radiation physicist who ensures that the physical and technical details can be implemented.

To further improve the conformality of the dose distribution, especially around concave targets, a more advanced 3D-CRT planning system, called *intensity-modulated radiation therapy (IMRT)*, can be used (Fig. 28-7). As a result of this improved conformality, IMRT has the potential to decrease bowel and bladder toxicity during pelvic radiation therapy (Heron, 2003). IMRT modulates the intensity of radiation beams to be used with the help of dedicated computer software. For quality assurance, weekly or sometimes even daily imaging of the treated regions is performed to verify that treatment configurations are correct.

Stereotactic Body Radiation Therapy. Over the past decade, a novel external beam radiation therapy technique, *stereotactic body radiation therapy (SBRT)*, has become commonly used in sites such as the lung, liver, and spine. It uses a hypofractionated regimen of five or fewer fractions (10 to 20 Gy per fraction). Using *image-guided radiation therapy (IGRT)*, precise, safe SBRT and IMRT have become possible through "real-time" approaches to overcome technical factors such as patient or organ motion and tumor size and shape changes during a treatment course.

Brachytherapy

Brachytherapy means treatment at a short distance. During this therapy, sealed or unsealed radioisotopes are inserted into the cancer or its immediate vicinity. Radiation doses fall sharply with increasing distances from the radioactive source. Thus, brachytherapy is indicated only for small tumor volumes (less than 3 to 4 cm). For this reason, brachytherapy is typically practiced after external beam radiation therapy has decreased a large tumor volume.

Brachytherapy may be intracavitary or interstitial. During *intracavitary brachytherapy*, applicators that hold sealed radioactive sources such as iridium-192 (^{192}Ir) are inserted into a body cavity such as the uterus. Alternatively, *interstitial brachytherapy* requires the placement of catheters or needles directly into the cancer and surrounding tissues.

Brachytherapy may be temporary or permanent. In *temporary brachytherapy*, the radioisotopes are removed from the patient after a period of time, ranging from minutes to days. All intracavitary and some interstitial implants are temporary. In *permanent brachytherapy*, the radioisotopes are left permanently to decay within the tissues.

Equipment. For routine gynecologic intracavitary implantation, standard equipment includes an applicator, called a *tandem*, which fits into the uterine cavity, and a pair of vaginal applicators, which are known as *ovoids* (Fig. 28-8). The tandem and ovoid device (T&O) is inserted under general anesthesia or conscious sedation. Following placement, radioactive sources can then be loaded into both the tandem and ovoids. In gynecologic oncology, brachytherapy with T&O is indicated for cervical cancer. For uterine cancer, vaginal brachytherapy with a cylinder is used to treat the vaginal apex or length of the vagina, which is the most common site of disease recurrence after hysterectomy (Fig. 28-9).

For temporary interstitial implantation, flexible plastic catheters or metal needles are surgically placed into the target

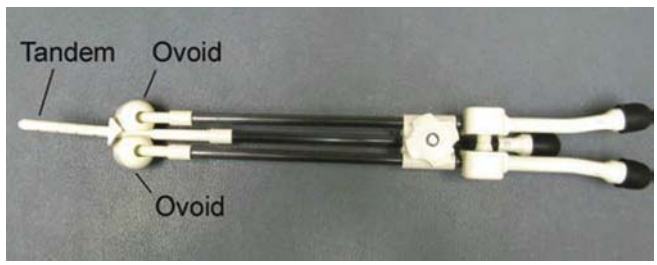


FIGURE 28-8 Computed tomography/magnetic resonance–compatible tandem and ovoids used for cervical cancer brachytherapy. The long slender portion of the device (tandem) is inserted into the endometrial cavity, and white cylinders (ovoids) are positioned in the proximal vagina. Radioactive sources can be loaded into both the tandem and ovoid reservoirs.

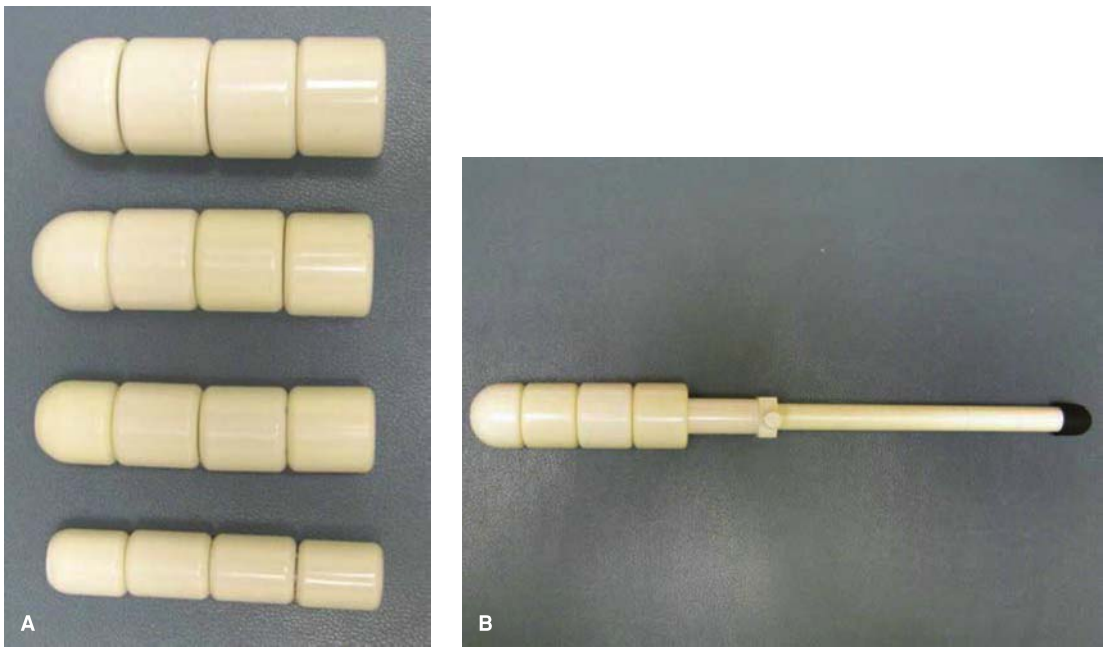

FIGURE 28-9 Computed tomography/magnetic resonance–compatible cylinders **(A)** come in different sizes to allow the most appropriate fit for the patient's anatomy. The largest possible diameter is preferred. **B.** The cylinder is used for vaginal brachytherapy after surgery for uterine cancer. It is placed in the vagina and high dose-rate brachytherapy is delivered. This treatment decreases the risk of vaginal cuff recurrences.

tissues and held in place by a perineal template. These are then afterloaded with ^{192}Ir seeds. Templates are suitable for patients with advanced cancers, suboptimal anatomy for T&O application, and selected recurrent cancers.

In addition to T&O, vaginal cylinder, and interstitial needles, physicians may choose to use a tandem and ring, split-ring, or tandem and cylinder. Appropriate brachytherapy applicator selection requires expertise, as applicator choice depends on patient anatomy and a specific device's dose distribution.

Manual versus Remote Afterloading. Once the brachytherapy instruments are in place, the radioactive sources are inserted. Historically, the sources were placed manually, however, this method increased hospital staff radiation exposure. Subsequently, a *remote afterloading* approach was developed and is commonly practiced today. This remote control system delivers a single miniaturized iridium source from a protective safe through connecting cables to the holding devices previously inserted into the patient. Following treatment, the radioactive source is automatically retracted back into the safe**.**

Low Dose-Rate versus High Dose-Rate Brachytherapy. Traditionally, low dose-rate (LDR) brachytherapy is delivered over the course of many days and requires patient hospitalization. Over the past few decades, however, high-dose-rate (HDR) brachytherapy has become more popular. With this technique, treatment is shortened to minutes. Low dose is defined as dose rates from 0.4 Gy to 2 Gy/hr, and high dose describes dose rates higher than 12 Gy/hr. For example, with an intracavitary implant for cervical cancer and an LDR technique, a dose of 30 to 40 Gy is delivered continuously over several days. In contrast, with HDR, an equivalent dose can be delivered in 3 to 5 weekly fractions. The dose per fraction is 5 to 7 Gy and can be given in 10 to 20 minutes. Unlike LDR, HDR avoids lengthy inpatient hospitalization and minimizes patient immobility and thromboembolic events. Furthermore, long-term analysis shows similar local tumor control and late complication rates in patients treated for cervical cancer with both HDR and LDR (Arai, 1991; Hareyama, 2002; Wong, 2003).

Tumor Control Probability

With most epithelial cancers, the probability that radiation therapy will control a cancerous mass depends on the tumor's size and intrinsic radiosensitivity and on the radiation dose and delivery schedule. For example, within a given stage, large tumors are more difficult to control with radiation than smaller ones (Bentzen, 1996; Dubben, 1998).

Intrinsic Radiosensitivity

It is recognized that a tumor's radiosensitivity in general is determined by its pathologic type (Table 28-3). However, even cancers with a similar histology may have variable responses to radiation. This may be explained by heterogeneity within a given tumor and by the cancer cell's ability to repair radiation damage (Schwartz, 1988, 1996; Weichselbaum, 1992).

TABLE 28-3. Radiosensitivity of Some Selected Cancers

Sensitivity	Cancer Type
Highly sensitive	Lymphoma, dysgerminoma, small cell cancer, embryonal cancer
Moderately sensitive	Squamous carcinoma, adenocarcinoma
Poorly sensitive	Osteosarcoma, glioma, melanoma

Treatment Time

When protracted time intervals are required to complete a fractionated radiation therapy course, tumor control probability decreases, especially in rapidly proliferating epithelial cancers. Thus, treatment breaks or delays for any reason are minimized. In a retrospective review of 209 patients with stage I to III cervical cancer treated with radiation therapy, the 5-year pelvic control and overall survival rates were better for those who completed the treatment in less than 55 days (87 percent and 65 percent, respectively) than for those who did so in more than 55 days (72 percent and 54 percent, respectively) (Petereit, 1995).

Tumor Hypoxia

Tumor hypoxia is a major factor leading to poor local tumor control and poor survival rates in patients with cervical cancer (Brizel, 1999; Nordsmark, 1996). The close relationship between tumor hypoxia, anemia, and angiogenesis was demonstrated in a study involving 87 patients with stage II, III, and IV cervical cancer treated with radiation only. Of these, patients with hemoglobin levels <11 g/dL and a median tumor oxygen tension pO_2 <15 mm Hg had decreased 3-year survival rates (Dunst, 2003).

To overcome tumor hypoxia, many strategies have been devised and vary in efficacy. Of these, hyperbaric oxygen used in conjunction with radiation therapy in cervical cancer was not effective in clinical studies (Dische, 1999). An alternate method to increase oxygen delivery to tissues manipulates blood vessel hemodynamics with either inhaled carbogen (95 percent oxygen and 5 percent carbon dioxide) or nicotinamide (a vasoactive agent). This approach of *accelerated radiotherapy with carbogen and nicotinamide (ARCON)* improves tumor control in patients with anemia but is not commonly used (Janssens, 2014).

Another approach to minimize tumor hypoxia effects employs *bioreductive agents*. This family of hypoxic cell sensitizers selectively kills hypoxic cells. Earlier findings with one of these, tirapazamine (TPZ), was encouraging. However, results of a Gynecologic Oncology Group (GOG) Phase III trial that evaluated TPZ, cisplatin, and radiation therapy compared with cisplatin and radiation show no improvement in survival or tumor control rates for patients with cervical cancers (DiSilvestro, 2014).

Last, to ensure adequate oxygen carrying capacity, a hemoglobin level of at least 12 g/dL is desirable in patients receiving radiation therapy. To this goal, transfusion ameliorates tumor hypoxia and increases radiation response. In a study of 204 women with cervical cancer who were treated with radiation, those who were transfused to maintain a hemoglobin level >11 g/dL had a similar 5-year disease-free survival rate (71 percent) compared with a group of women who never required transfusion. The disease-free survival rate was only 26 percent for those with persistent anemia (Kapp, 2002). The use of erythropoietin to maintain hemoglobin above 12 g/dL was also tested in a randomized trial of patients with cervical cancer receiving chemotherapy and radiation. This trial closed early due to higher rates of thromboembolism with erythropoietin use (Thomas, 2008).

Ionizing Radiation and Chemotherapy

Radiation is often combined with chemotherapy, surgery, or both to improve local disease control and decrease distant metastasis. Radiation therapy and chemotherapy can be administered in a concurrent or alternating fashion to maximize tumoricidal effects and minimize overlapping toxicities and complications (Steel, 1979). This practice is supported by results from many controlled studies involving cervical and other cancers.

In the management of gynecologic cancers, platinum compounds are most commonly used with radiation therapy. Both radiation and cisplatin cause single- and double-strand DNA breaks and base damage. Although most lesions are repaired, if cisplatin-induced DNA damage lies close to a radiation-induced single-strand break, then the damage is irreparable and leads to cell death (Amorino, 1999; Begg, 1990). Since the late 1990s, the standard treatment for newly diagnosed locally advanced cervical cancer has been radiation therapy and cisplatin (Keys, 1999; Morris, 1999; Rose, 1999).

Nucleoside analogues such as fludarabine and gemcitabine also are used to enhance the effects of radiation-induced cell killing. These agents inhibit DNA synthesis by blocking cells at the G_1/S checkpoint. The remaining cell population is synchronized at the G_2/M junction, the most radiation-sensitive phase of the cell cycle. Clinically, in a Phase III study of cervical cancer patients, the progression-free survival and overall survival rates improved in patients randomized to receive gemcitabine, cisplatin, and radiation followed by adjuvant gemcitabine compared with cisplatin and radiation alone (Duenãs-González, 2011). However, inclusion of gemcitabine is still considered investigational for cervical cancer treatment.

Taxanes, such as paclitaxel and docetaxel, enhance the effects of radiation by causing microtubule dysfunction and blocking cells at the G_2/M junction (Mason, 1999). Taxanes have been administered with platinum agents and radiation therapy in small nonrandomized trials involving patients with locally advanced cervical cancer (Lee, 2007).

Radiation Therapy and Surgery

Radiation therapy can be given before, after, or at the time of surgery. With this combination, surgical resection and its associated morbidity can often be minimized.

Preoperative adjuvant radiation, which is radiation prior to surgery, may offer several advantages for tumor control. First, primary cancers tend to locally infiltrate surrounding normal tissues with microscopic extension. Accordingly, radiation can be delivered prior to surgery to decrease the potential for locoregional and distant tumor dissemination and the likelihood of positive surgical margins. To sterilize areas of subclinical infiltration, doses of 40 to 50 Gy administered over 4 to 5 weeks are required. Although preoperative radiation therapy is not expected to render the main tumor mass cancer-free at the time of surgery, it is common to find no evidence of cancer in the surgical specimen. Second, the combination of radiation and surgery in locally advanced vulvovaginal cancer can allow surgeons to avoid extensive surgery such as pelvic exenteration (Boronow, 1982). Last, in patients who present with unresectable cancers, preoperative radiation therapy can transform them

into suitable candidates for a surgical attempt (Montana, 2000). Surgery is usually delayed 4 to 6 weeks after radiation completion. By then, the acute radiation reactions have subsided, and pathologic interpretation of the resected specimen is easier.

Two studies by the GOG (GOG 71 and 123) have investigated preoperative radiation and chemoradiation, respectively, in patients with bulky stage IB cervical cancer (Keys, 1999, 2003). In both trials, the pathologic complete response rate, defined as no residual disease in a resected specimen, approximated 50 percent.

Postoperatively, a high probability for local recurrence may often be predicted by factors such as positive margins, lymph node metastases, lymphovascular invasion, and high-grade disease. In these cases, postoperative radiation therapy may be beneficial and is ideally delivered 3 to 6 weeks following surgery. This delay allows initial wound healing (Sedlis, 1999). The radiation fields should encompass the operative bed due to the possibility of tumor contamination at the time of surgery and adjacent areas that are at risk for tumor dissemination.

Postoperative radiation is employed in the treatment of many gynecologic malignancies. For cervical cancer, postoperative radiation is recommended in those with lymphovascular invasion, deep stromal invasion, or large tumor size (Sedlis, 1999). Postoperative chemoradiation is offered if positive parametria, positive margins, or positive lymph nodes are found. The addition of cisplatin and 5-fluorouracil to radiation in cervical cancer patients with these high-risk features has been shown to improve survival rates and tumor control (Peters, 2000).

For uterine cancer, postoperative radiation is frequently used for patients with stage IB or greater disease. Several large randomized controlled trials have demonstrated significant improvements in local control in patients with intermediate-risk endometrial adenocarcinoma who receive adjuvant pelvic radiation (ASTEC/EN.5 Study Group, 2009; Creutzberg, 2011; Keys, 2004). Intermediate risk includes older age, lymphovascular invasion, deep myometrial invasion, or intermediate- or high-grade disease. Patients with fewer risk factors can often be treated with vaginal brachytherapy alone. Vaginal brachytherapy treats the vaginal apex, where approximately 75 percent of recurrences are located. A randomized trial showed similar vaginal and pelvic tumor control rates with fewer side effects when vaginal brachytherapy alone was compared with pelvic external beam radiation therapy (Nout, 2010).

Intraoperative radiation therapy (IORT) is infrequently elected. It may be delivered either by interstitial brachytherapy or by an electron beam produced by a dedicated linear accelerator installed in the operating room. A single dose of 10 to 20 Gy is typically directed to the area at risk for recurrence or suspected of harboring residual cancer (Gemignani, 2001).

Further information on the role of radiation therapy in the treatment of gynecological malignancies is available in guidelines prepared by the American Society for Radiation Oncology and the American Brachytherapy Society (Beriwal, 2012; Lee, 2012a; Klopp, 2014; Jones, 2016; Small, 2012; Viswanathan, 2012a,b). Additionally, the American College of Radiology has formulated guidelines regarding the use of radiotherapy in specific gynecological malignancies (American College of Radiology, 2018).

Normal Tissue Response to Radiation Therapy

In general, radiation therapy is less well tolerated if: (1) the irradiated tissue volume is large, (2) the radiation dose is high, (3) the dose per fraction is large, and (4) the patient's age is advanced. Furthermore, the radiation damage to normal tissues can be exacerbated by factors such as prior surgery, concurrent chemotherapy, infection, diabetes mellitus, hypertension, and inflammatory bowel disease.

In general, if tissues with a rapid proliferation rate such as epithelium of the small intestine or oral cavity are irradiated, acute clinical symptoms develop within a few days to weeks. This contrasts with muscular, renal, and neural tissues, which have low proliferation rates and may not display signs of radiation damage for months to years after treatment. To avoid serious complications, radiation oncologists must use published tolerance doses for normal tissues as a guide and rely on their own clinical experience. For example, to avoid severe rectal and bladder complications in patients with cervical cancer, doses of no more than 65 Gy and 70 Gy are recommended to the rectum and bladder, respectively (Milano, 2007).

Epithelium and Parenchyma

Atrophy is the most consistent sequela of radiation therapy. It affects all lining epithelia—including skin and the epithelia of the gastrointestinal, respiratory, and genitourinary tracts and of the endocrine glands. Additionally, necrosis and ulceration may develop. Within the submucosa and deep soft tissues, fibrosis frequently follows radiation therapy, leading to tissue contracture and stenosis (Fajardo, 2005).

Of vascular structures, the capillary is the most radiosensitive, and ischemia results from endothelial damage, capillary wall rupture, loss of capillary segments, and reduction of microvascular networks. In large arteries, atheroma-like calcifications develop (Friedlander, 2003; Zidar, 1997).

Skin

Four general types of skin reactions may follow radiation therapy. In order of increasing severity, they include erythema, dry desquamation, moist desquamation, and skin necrosis. For many women during a 6- to 7-week radiation therapy course, the first three of these reactions are common. Within 2 weeks following radiation exposure, the skin develops mild erythema. By the fourth week, the redness becomes more pronounced and dry desquamation may begin. After 5 to 6 weeks, moist desquamation may follow. This involves epidermal sloughing, followed by serum and blood oozing through denuded skin. This reaction is mostly pronounced in skin folds, such as the inguinal, axillary, and inframammary creases.

Preventatively, throughout and after a radiation course, the skin is kept clean and aerated. For dry desquamation, ointments or aloe vera–containing creams promote dermal hydration with an emollient effect. During the moist desquamation phase, skin treatment may include moisturizers (e.g., Biafine), sitz baths, and silver sulfadiazine–containing, nonadhering dressings for weeping areas. Importantly, individuals are instructed to avoid applying heating pads, soaps, or alcohol-based lotions to irradiated skin.

Regeneration of the epithelium starts soon after radiation treatment and is usually complete in 4 to 6 weeks. Months later, areas of skin hyper- and hypopigmentation can be seen. The skin may remain atrophied, thin, and dry, and telangiectasias may be visible.

Vagina

Radiation therapy directed to the pelvis frequently leads to acute vaginal mucositis. Although mucosal ulceration is rare, discharge is present in most cases. For these women, a dilute hydrogen peroxide and water solution used at the vulva provides symptomatic relief.

In contrast, delayed reactions to radiation may include atrophic vaginitis, formation of vaginal synechiae or telangiectasia, and most commonly, vaginal stricture. Less frequently, rectovaginal or vesicovaginal fistulas may develop after radiation therapy, especially with advanced-stage cancers. Of these delayed reactions, Grade 3 vaginal stricture is defined by the Common Terminology Criteria for Adverse Events (CTCAE) as "vaginal narrowing and/or shortening interfering with the use of tampons, sexual activity or physical examination" (National Cancer Institute, 2017). Preventatively, vaginal stricture or synechiae may be avoided if intercourse is resumed following treatment or if women are instructed regarding dilator use. Dilators are inserted vaginally by the patient daily for 10 seconds, and this schedule continues from radiation therapy completion until the first follow-up visit at 6 weeks. At this point, weekly insertion or intercourse is recommended. Increased severe late vaginal toxicity is associated with poor dilator compliance, concurrent chemotherapy, and age >50 (Gondi, 2012). Importantly, stricture prevention also aids the ability to complete thorough vaginal examinations for cancer surveillance.

For women who remain sexually active following radiation therapy, water-based *vaginal lubricants* (e.g., Astroglide or K-Y Jelly) may be of benefit during intercourse but have no sustained effects. For chronic vaginal dryness, *vaginal moisturizers* may prove superior. Moisturizers (e.g., Replens and K-Y Silk-E) can be used daily or several times weekly to maintain moist vaginal tissues. Alternatively, topical estrogen cream (e.g., Premarin or Estrace cream) may improve atrophic symptoms in those who are estrogen candidates (Table 22-11, p. 498).

Despite these products, persistent adverse vaginal changes affect sexual dysfunction. In a study of 118 women treated for cervical cancer, 63 percent of those who engaged in sexual activities before radiation therapy continued to do so following treatment, although less frequently (Jensen, 2003). In a comparison of women treated with radiation versus radical hysterectomy and lymph node dissection for cervical cancer, women treated with radiation reported significantly lower sexual dysfunction scores than patients who underwent surgery (Frumovitz, 2005).

Ovary

The effects of radiation on ovarian function depend on radiation dose and patient age. For example, a dose of 4 Gy may sterilize 30 percent of young women but 100 percent of those older than 40. In addition, fractionated radiation therapy appears to be more damaging. Ash (1980) noted that after 10 Gy given in 1 fraction, 27 percent of the women recovered ovarian function compared with only 10 percent of those receiving 12 Gy over 6 days. In patients with gynecologic cancers who receive pelvic radiation therapy, symptoms of ovarian failure mirror those of natural menopause. The diagnosis and symptom treatment of premature ovarian insufficiency is outlined in Chapter 17 (p. 375).

To minimize radiation exposure to the ovaries of premenopausal women, the gonads may be surgically repositioned, termed *transposition,* out of the radiation fields. A review of prepubertal and adolescent girls undergoing transposition prior to pelvic radiation demonstrated long-term ovarian preservation rates ranging from 33 to 92 percent. However, only 11 of 347 women (3 percent) achieved pregnancy (Irtan, 2013).

Pregnancy Outcomes

Exposure to radiotherapy in childhood or adulthood does not significantly raise the risk for a congenital anomaly or genetic disease in their offspring (Seppänen, 2016; Signorello, 2012; Winther, 2012). However, prior childhood abdominopelvic radiation can affect pregnancy outcomes. Adverse effects include elevated rates of abortion, low birthweight, stillbirth, and preterm birth (Reulen, 2009; Signorello, 2010; Winther, 2008). Proposed explanations include reduced uterine volume, endometrial and myometrial atrophy, fibrosis, and impaired uterine blood flow (Arrivé, 1989; Critchley, 1992).

Bladder

Most patients receiving pelvic radiation note some acute cystitis symptoms within 2 to 3 weeks of beginning treatment. Although urinary frequency, spasm, and pain develop commonly, hematuria is rare. Typically, phenazopyridine hydrochloride (Pyridium) or fluid ad lib promptly relieves symptoms. Antibiotics are prescribed when indicated. Major chronic complications following radiation therapy are infrequent and include bladder contracture and hematuria. For severe hematuria, bladder saline irrigation, transurethral cystoscopic fulguration, and temporary urinary diversion are proven techniques. Fistulas involving the bladder typically require urinary diversion.

Small Bowel

The small bowel is particularly vulnerable to acute early damage from radiation therapy. After a single dose of 5 to 10 Gy, crypt cells are destroyed, and villi become denuded. An acute malabsorption syndrome ensues to cause nausea, diarrhea, vomiting, and cramping. Adequate fluid intake and a low-lactose, low-fat, and low-fiber diet is recommended. Additionally, antinausea and antidiarrheal medications may be warranted (Tables 25-5, p. 566, and 42-9, p. 916). Bowel antispasmodics with sedatives (e.g., Donnatal) are particularly helpful.

Patients are warned about the late, chronic nature of radiation-induced enteritis. Intermittent diarrhea, crampy abdominal pain, nausea, and vomiting, which in combination may mimic a low-grade bowel obstruction, can develop. Those patients with comorbidities, such as obesity, small-vessel diseases resulting from diabetes or hypertension, prior abdominal surgeries, and inflammatory conditions of the pelvis or bowel, are at greater risk.

Preventatively, several types of devices have been surgically inserted to displace the small bowel from the pelvis. These have included saline-filled tissue expanders, omental slings, and absorbable mesh (Hoffman, 1998; Martin, 2005; Soper, 1988). Furthermore, defining the areas at risk with surgical clips and careful radiation therapy planning, including the use of IMRT, may minimize bowel toxicity (Portelance, 2001). Consideration of dose constraints can further minimize injury. Studies show that irradiating a volume larger than 15 cm^3 or a point dose greater than 55 Gy is associated with a significant risk of small bowel damage (Stanic, 2013; Verma, 2014). Radiation treatment with patients prone also can limit the small bowel dose (Adli, 2003). In contrast, trials incorporating radiation protectors, such as amifostine, have been unsuccessful (Small, 2011).

Rectosigmoid

Commonly, within a few weeks after radiation therapy initiation, patients may develop diarrhea, tenesmus, and mucoid discharge, which can be bloody. In these cases, antidiarrheal medications, low-residue diet, steroid-retention or sucralfate enemas, and hydration are management mainstays. Alternatively, rectal bleeding may be seen months to years after radiation therapy. Hemorrhage can at times be severe and require blood transfusion. Moreover, invasive procedures may be needed to control bleeding neovasculature. These include the topical application of 4-percent formalin, cryotherapy, and vessel coagulation with laser (Kantsevoy, 2003; Konishi, 2005; Smith, 2001; Ventrucci, 2001). During the evaluation of late-onset rectal bleeding, barium enema is often indicated. The study usually reveals narrowing of the rectosigmoid lumen and wall thickening. In cases of severe obstruction, resection of the involved colonic segment is necessary. In addition, rectovaginal fistulas may result from radiation therapy (Chap. 25, p. 570). Small fistulas may heal over many months following a diverting colostomy.

Brachytherapy, in addition to external beam radiation, can further escalate rectal toxicity. The D2cc metric (minimum dose to the most irradiated contiguous volume of 2 cc) is commonly used to evaluate the rectal dose in brachytherapy. Doses >62 Gy are associated with higher rates of Grade 2 to 4 rectal toxicities (Lee, 2012b). This metric was developed as part of the GEC-ESTRO (Groupe Européen de Curiethérapie—European Society of Therapeutic Radiation Oncology) guidelines, which provide dose-reporting parameters for the bladder, rectum, and sigmoid colon using 3-D image-based treatment planning (Potter, 2006).

Kidney

Manifestations of acute radiation nephropathy typically appear 6 to 12 months after radiation exposure. Affected patients develop hypertension, edema, anemia, microscopic hematuria, proteinuria, and decreased creatinine clearance (Luxton, 1964). Although deteriorating renal function is occasionally reversible, it usually worsens and leads to chronic nephropathy. Patients receiving concurrent radiation and chemotherapy require special consideration because of the nephrotoxicity associated with many chemotherapeutics (Chap. 27, p. 592).

Bone

Radiation-induced insufficiency fractures are not infrequent following pelvic radiation. They develop in weakened bone and typically manifest as pain. The sacrum is most commonly involved (Cooper, 1985). Rates are higher in patients receiving definitive radiation therapy, and in a large series of 557 patients with cervical cancer, 20 percent developed insufficiency fractures over 5 years (Oh, 2008). In a more recent series of 222 patients receiving postoperative pelvic radiation therapy, only 5 percent developed pelvic insufficiency fractures. These developed at a median time of 11.5 months after radiation therapy completion (Shih, 2013). The fracture rate was higher in patients with osteoporosis (16 percent), in those on hormone replacement therapy (15 percent), and in patients with a lower body mass index. Treatment for a pelvic insufficiency fracture is conservative and consists of pain management and rest, with most patients becoming symptom free by 20 months.

Hematologic Toxicity

Radiation therapy can significantly deplete bone marrow hematopoietic stem cells that include erythrocyte, leukocyte, and platelet precursors. These effects are exacerbated by combined chemoradiation or by irradiation of large fields that contain a significant portion of bone marrow. Accordingly, there are thresholds at which radiation is held to prevent further bone marrow suppression. For example, if platelet levels measure $<35{,}000 \times 10^9$/L and leukocyte counts are $<1.0 \times 10^9$/L, then radiation may be held until these values rise. For anemia, transfusion is recommended (p. 614). To spare bone marrow injury, IMRT may be beneficial (Klopp, 2013).

Radiation-Induced Carcinogenesis

A secondary cancer may develop as a result of prior radiation therapy. The accepted criteria for the diagnosis of radiation-induced cancer require that the cancer be located within the previously irradiated region and that its pathology differ from that of the original malignancy. Additionally, a latent period of at least a few years should have transpired. In the updated analysis of the Post-Operative Radiation Therapy in Endometrial Carcinoma (PORTEC-1) trial, which compared postoperative adjuvant pelvic radiation against observation, the secondary cancer rates at 15 years were 22 percent in the radiation group compared with 16 percent in the observation group. However, this difference did not reach statistical significance (Creutzberg, 2011).

Development of a secondary radiation-induced cancer depends on factors such as patient age at exposure, radiation dose, and susceptibility of specific tissue types to radiation-induced carcinogenesis (Table 28-4). In general, those receiving higher radiation doses and those exposed at an earlier age have higher risks for second malignancies. The latency of secondary

TABLE 28-4. Susceptibility of Selected Tissues to Radiation-Induced Cancer

Susceptibility	Tissues
High	Bone marrow, female breast, thyroid
Moderate	Bladder, colon, stomach, liver, ovary
Low	Bone, connective tissue, muscle, cervix, uterus, rectum

tumor development also varies depending on the type of second malignancy. For example, the latent period between radiation exposure and the clinical appearance of leukemia is less than 10 years, whereas solid tumors may not develop for decades. The most common example is development of uterine sarcoma years after pelvic radiation for treatment of cervical cancer (Mark, 1996). Preventatively, irradiation of smaller fields with advanced technologies such as IMRT compared with larger-field 2-D external beam radiation may reduce the incidence of radiation-induced malignancies (Herrera, 2014).

Office gynecology includes the diagnosis and management of preinvasive lower anogenital tract (LAGT) disease, most often involving the uterine cervix, but also the vulvar, vaginal, perianal, and anal epithelia. An understanding of human papillomavirus (HPV) as the causative agent of most LAGT neoplasia has greatly advanced screening, diagnosis, management, and prevention efforts. Importantly, in current clinical practice, evidence-based knowledge is ever evolving and translates into rapidly changing patient-care recommendations. Although most study findings and clinical guidelines to date refer to women, these are applicable to the care of some transgender men (Hembree, 2017).

LOWER ANOGENITAL TRACT NEOPLASIA

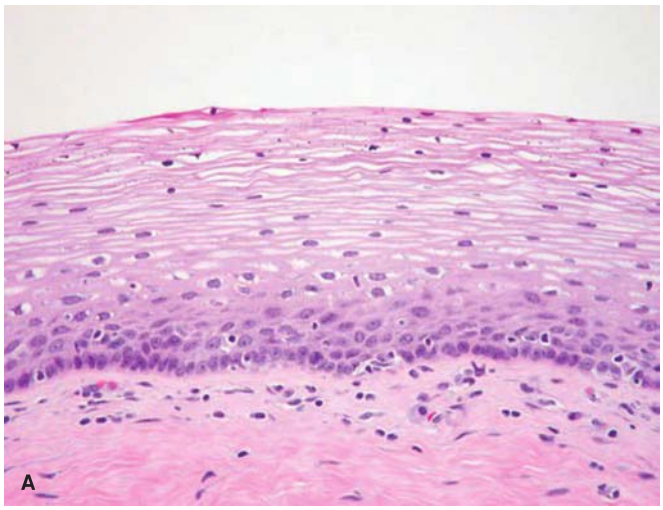
In the LAGT, the term *intraepithelial neoplasia* refers to epithelial lesions that are potential precursors of invasive cancer. These lesions demonstrate a range of histologic abnormality from mild to severe based on cytoplasmic, nuclear, and histologic changes. The severity of squamous intraepithelial lesions is graded by the proportion of epithelium with abnormal cells. These alterations begin at the basement membrane and continue upward toward the epithelium surface. With cervical intraepithelial neoplasia (CIN), abnormal cells solely confined to the lower third of the squamous epithelium are referred to as *mild dysplasia* or *CIN 1*. Those that extend into the middle third are *moderate dysplasia* or *CIN 2;* into the upper third, *severe dysplasia* or *CIN 3;* and full-thickness involvement, *carcinoma in situ (CIS)* (Fig. 29-1). Preinvasive squamous lesions of the vagina, vulva, perianal, and anal squamous epithelia are graded similarly to CIN. The natural history of these extracervical lesions is less understood than for CIN. In contrast, the cervical columnar epithelium does not demonstrate an analogous neoplastic disease spectrum because it is only one cell layer thick. Histologic abnormalities are therefore limited to those that are contained in the columnar epithelium, *adenocarcinoma in situ (AIS),* or those that invade past the epithelial basement membrane, *adenocarcinoma*.

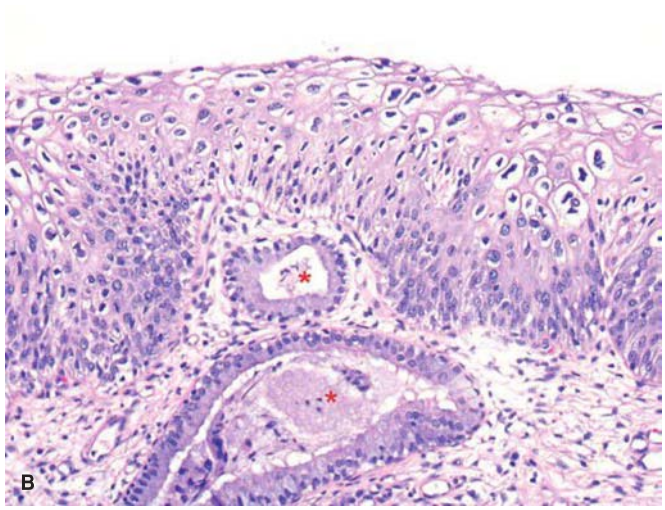
The concept of cervical neoplasia (preinvasive and invasive) as a spectrum has come under question with increasing insight into HPV infection. Mild squamous dysplasia is now recognized as evidence of HPV infection, most of which is transient and unlikely to progress. Moderate to severe dysplastic squamous lesions are considered to be true cancer precursors, especially CIN 3. Current cytologic and histologic reporting reflects this two-tiered concept (Darragh, 2012; Solomon, 2002). In 1989, the Bethesda System cytologic nomenclature replaced CIN with *squamous intraepithelial lesion (SIL)*. Because cytologic and histologic changes of HPV infection and CIN 1 are not distinguished reliably and because their natural histories are similar, they are categorized together as *low-grade squamous intraepithelial lesions (LSIL)*. Similarly, CIN 2, CIN 3, and CIS are difficult to distinguish, are truer cancer precursors, and are designated together as *high-grade squamous intraepithelial lesion (HSIL)*. The diagnostic distinction between LSIL and HSIL is more reliable, biologically plausible, and clinically meaningful than diagnoses using the CIN system. This two-tiered nomenclature is now recommended for histology as well, and guidelines for the management of these lesions are grouped accordingly (Darragh, 2012).

ANATOMIC CONSIDERATIONS

External Genitalia

Precancerous lesions of the female LAGT are often multifocal, can involve any of its structures, and may appear similar to benign processes. For example, *micropapillomatosis labialis* is a benign anatomic variant characterized by minute epithelial projections on the inner labia minora (Fig. 29-2). This condition can be easily mistaken for HPV-related lesions. Instead, true HPV lesions tend to be multifocal, asymmetric, and show multiple papillations arising from a single base (Ferris, 2004). Micropapillomatosis often shows spontaneous regression, and treatment is not indicated (Bergeron, 1990).





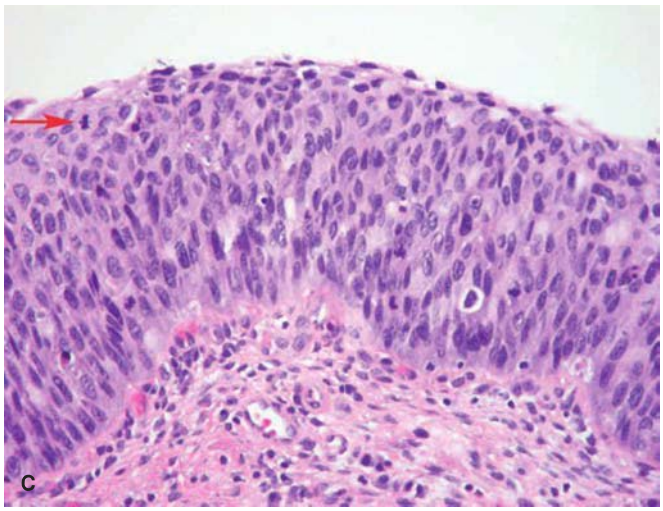


FIGURE 29-1 A. Normal ectocervical epithelium is a nonkeratinizing, stratified, squamous epithelium, which contains basal, parabasal, intermediate, and superficial layers. The epithelium matures and accumulates glycogen in its upper layers. Mitoses are usually confined to the parabasal layer. **B.** Low-grade squamous intraepithelial lesion (LSIL). This biopsy's location at the transformation zone is indicated by the presence of both mucinous columnar endocervical epithelium (*asterisks*) and squamous epithelium. LSIL has disordered squamous cell proliferation and increased mitotic activity confined to the basal one third of the epithelium. Koilocytotic atypia, indicative of proliferative human papillomavirus (HPV) infection, involves the more superficial epithelium. Koilocytosis is typified by nuclear enlargement, coarse chromatin, nuclear "wrinkling," perinuclear halos, and greater prevalence of binucleation/multinucleation. **C.** High-grade squamous intraepithelial lesion (HSIL). This example shows disordered, markedly atypical squamous cells and increased mitotic activity that involves the epithelium's full thickness. Note the mitotic figure located close to the epithelial surface (*red arrow*). (Reproduced with permission from Dr. Kelley Carrick.)

Vagina

The vagina is lined by nonkeratinized squamous epithelium, and glands are absent. However, islands of columnar epithelium are occasionally found within the vaginal squamous mucosa, a condition termed *adenosis*. It can result from in utero exposure to exogenous estrogen, particularly diethylstilbestrol (DES) (Trimble, 2001). Appearing as red patches within the squamous epithelium, these can be mistaken for ulcers or other lesions.

Vaginal adenocarcinoma may arise within adenosis. Of primary vaginal adenocarcinomas, the clear cell type is most closely associated with DES exposure. Thus, with DES-related adenosis, careful palpation of the vagina is warranted in addition to visual inspection, as clear cell adenocarcinoma may be palpable before becoming visible.

Cervix

Squamocolumnar Junction

During embryogenesis, upward migration of stratified squamous epithelium from the urogenital sinus is thought to replace müllerian epithelium (Ulfelder, 1976). This process usually terminates near the external cervical os, forming the original (congenital) squamocolumnar junction (SCJ). When visible on the ectocervix, the SCJ is seen as a pink, smooth, squamous epithelium juxtaposed against the red, velvety, columnar epithelium surrounding the external cervical os. Rarely, this migration is incomplete, and the SCJ forms in the upper vaginal fornices. This normal variant is also seen with in utero DES exposure.

The columnar epithelium is commonly referred to as "glandular." It does produce mucus, and its deep infoldings appear histologically similar to glandular tissue (Fig. 29-3). However, true glands, which consist of acini and ducts, are not present on the cervix (Ulfelder, 1976).

The location of the SCJ varies with age and hormonal status. During the reproductive years, it everts outward onto the ectocervix in response to estrogen (especially during adolescence, pregnancy, and combination hormonal contraceptive use). It regresses into the endocervical canal with the process of squamous metaplasia and low-estrogen states like menopause, lactation, and progestin-only contraceptive use.

Squamous Metaplasia

At puberty, the rise in estrogen levels leads to greater glycogen formation within nonkeratinized cervical and vaginal squamous epithelia. In providing a carbohydrate source, glycogen allows vaginal flora to be dominated by lactobacilli, which produce lactic acid. The resultant acidic vaginal pH is the suspected

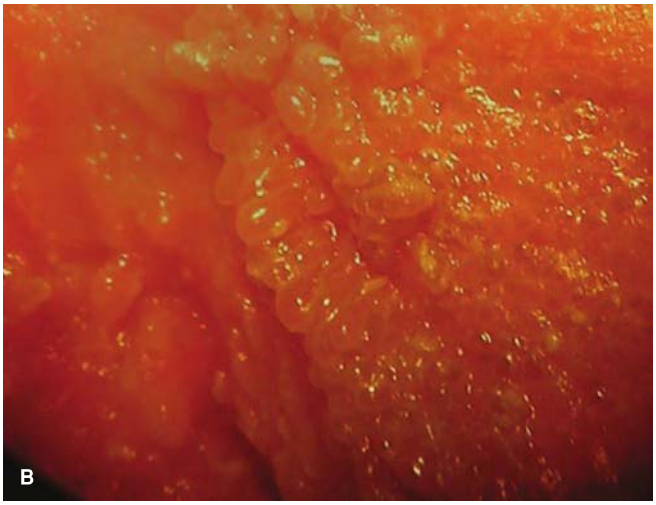

FIGURE 29-2 Benign lower genital tract lesions. **A.** Condylomata tend to be multifocal and asymmetric and have multiple papillations arising from a single base. **B.** Micropapillomatosis labialis is a normal variant of vulvar anatomy encountered along the inner labia minora and lower vagina. In contrast to condylomata, projections are uniform in size and shape and arise singly from their base attachments.

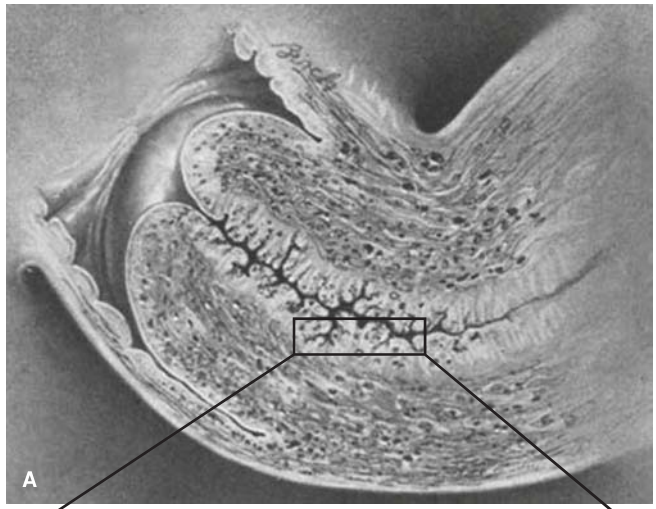

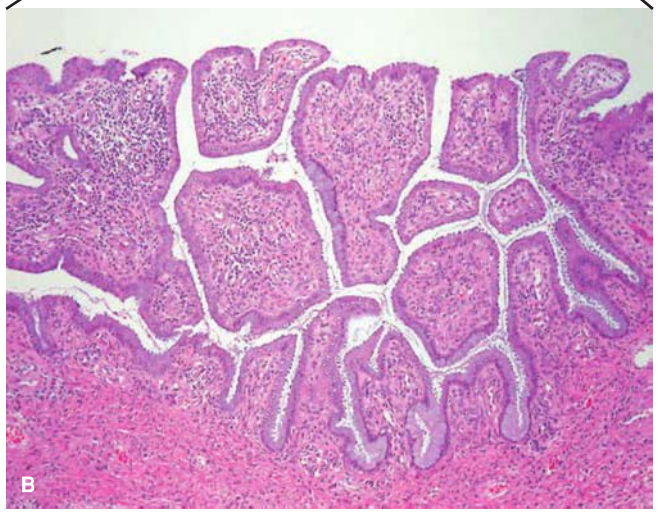

FIGURE 29-3 Endocervical anatomy. **A.** Sagittal view of the cervix. In this drawing, a portion of the endocervical canal is boxed. (Modified and reproduced with permission from Eastman, 1961.) **B.** The endocervix is lined by a simple, columnar, mucin-secreting epithelium. Crypts and small exophytic projections appear pseudopapillary when viewed in cross section. (Reproduced with permission from Dr. Kelley Carrick.)

stimulus for *squamous metaplasia*, which is the normal replacement of columnar by squamous epithelium on the cervix. Undifferentiated reserve cells underlying the SCJ are the likely precursors of the new metaplastic cells, which differentiate further into squamous epithelium. This normal process creates a progressively widening band of newer metaplastic and maturing squamous epithelium that lies between the original squamous epithelium and the columnar epithelium and is termed the *transformation zone (TZ)* (Fig. 29-4).

Transformation Zone and Cervical Neoplasia

Nearly all cervical neoplasia, both squamous and columnar, develops within the TZ, usually adjacent to the new or current SCJ. Cervical reserve and immature metaplastic cells appear most vulnerable to the oncogenic effects of HPV and co-carcinogens (Stanley, 2010a). Squamous metaplasia is most active during adolescence and pregnancy. This may explain why sexual activity and first pregnancy at an earlier age are cervical cancer risk factors.

HUMAN PAPILLOMAVIRUS

Basic Virology

The causative role of HPV in nearly all cervical neoplasia (both squamous and glandular) and in a significant proportion of vulvar, vaginal, and anal squamous neoplasias is firmly established (zur Hausen, 2009). HPV causes nearly all cervical cancers and approximately 90 percent of anal cancers, 70 percent of vaginal, and 40 percent of vulvar cancers. HPV primarily infects human squamous or metaplastic epithelial cells. It is a double-stranded DNA virus with a protein capsid unique to each viral type. More than 150 genetically distinct HPV types have been identified, and approximately 40 types infect the LAGT (Doorbar, 2012).

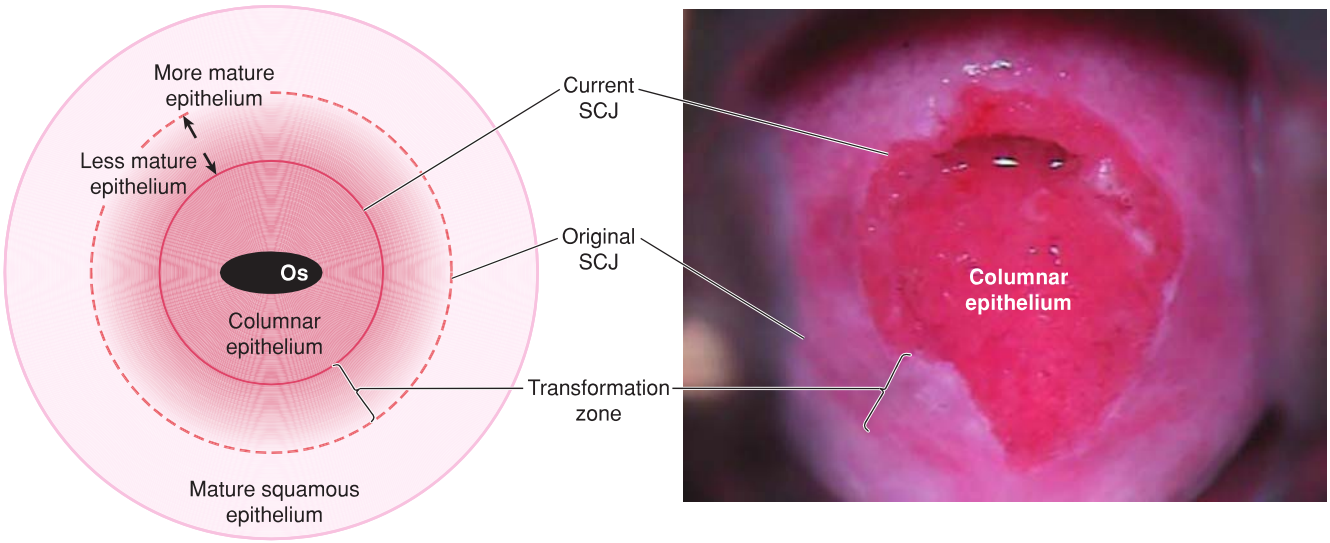

FIGURE 29-4 Relevant ectocervical landmarks depicted in a schematic drawing and corresponding photograph.

The circular HPV genome consists of only nine identified open reading frames (Stanley, 2010a). In addition to one regulatory region, the six "early" (E) genes govern functions early in the viral life cycle, including DNA maintenance, replication, and transcription. Early genes are expressed in the lower squamous epithelial layers (Fig. 29-5). The two "late" genes encode the major (L1) and minor (L2) capsid proteins. These proteins are expressed in the superficial epithelial layers late in the viral life cycle and during the assembly of new, infectious viral particles. Sequential HPV gene expression is synchronous with and dependent on squamous epithelial differentiation. Thus, completion of the viral life cycle takes place only within an intact, fully differentiating squamous epithelium (Doorbar, 2012). For this reason, HPV is not readily cultured in vitro. HPV is not released by pathogenic viral lysis, and infectiousness depends on normal desquamation of infected epithelial cells. A new infection is initiated when the L1 and L2 capsid proteins bind to the epithelial basement membrane or basal cells, which permits entry of HPV viral particles into cells of a new host (Sapp, 2009).

Clinically, HPV types are classified as high-risk (hrHPV) or low-risk (lrHPV) based on the strength of their association with cervical cancer. LrHPV types 6 and 11 cause nearly all genital warts, laryngeal papillomas, and a substantial minority of subclinical HPV infections and cytology abnormalities. LrHPV infections are rarely, if ever, oncogenic.

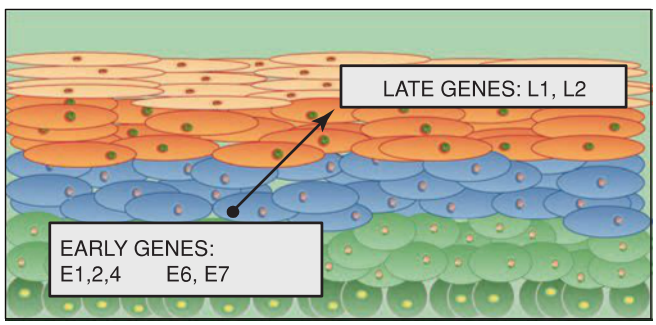

FIGURE 29-5 The human papillomavirus life cycle is completed in synchrony with squamous epithelium differentiation. Early genes, including the *E6* and *E7* oncogenes, are expressed most strongly within the basal and parabasal layers. The late genes encoding capsid proteins are expressed later in the superficial layer. Intact virus is shed during normal desquamation of superficial squames. Late genes are not strongly expressed in high-grade neoplastic lesions.

In contrast, persistent hrHPV infection is viewed as requisite for cervical cancer development. HrHPV types, including 16, 18, 31, 33, 35, 45, and 58, along with a few less-common types, account for approximately 95 percent of cervical cancer cases worldwide (Muñoz, 2003). HPV 16 is the most oncogenic and accounts for the largest percentage of CIN 3 lesions (45 percent) and cervical cancers (55 percent). It is also the dominant type linked to other HPV-related anogenital and oropharyngeal cancers (Schiffman, 2010; Smith, 2007). Although the prevalence of HPV 18 is much lower than that of HPV 16 in the general population, this type is found in 13 percent of cervical squamous cell carcinomas, and in an even higher proportion of cervical adenocarcinomas and adenosquamous carcinomas (approximately 40 percent) (Bruni, 2010; Smith, 2007). Together, HPVs 16 and 18 account for approximately 70 percent of cervical cancers worldwide, 68 percent of squamous cell carcinomas, and 85 percent of adenocarcinomas (Bosch, 2008). HPV type 45 is the third most common type found in cervical cancers (de Sanjose, 2019). Prior to HPV vaccination (pre-2006), HPVs 16 and 18 accounted for 1 in 5 cervical HPV infections in women. These were the most common HPVs found among low-grade lesions and in women without neoplasia (Bruni, 2010; Herrero, 2000). Thus, hrHPV infection does not cause neoplasia in most infected women, and additional host, viral, and environmental factors determine progression to LAGT neoplasia.

Epidemiology

Genital HPV is the most common sexually transmitted disease (STD) in the United States, and most sexually active adults are infected at some time (Dunne, 2014). U.S. women aged 14 to 59 years have a prevalence of genital HPV infection that approximates 40 percent (Hirth, 2019). Infection with HPV, predominantly high-risk types, is common soon after sexual

activity initiation (Brown, 2005; Winer, 2003). Infection often accompanies sexual debut and should not be equated with promiscuity (Collins, 2002). Most incident HPV infections are found in women younger than 25 years. Prevalence is highest in those aged 20 to 24 years (45 percent) and decreases with age (Dunne, 2007). Young women frequently change HPV types, and this reflects infection transience and sequential reinfection by new partners rather than persistence (Ho, 1998; Rosenfeld, 1992). Simultaneous or sequential infection with multiple HPV types is common (Schiffman, 2010).

The most important risk factors for genital HPV acquisition are number of lifetime and recent sexual partners and early age of first sexual intercourse (Burk, 1996; Fairley, 1994; Franco, 1995). Genital HPV is transmitted by direct, usually sexual contact with the genital skin, mucous membranes, or body fluids of a person with HPV infection. The infectivity of inapparent (subclinical) HPV is assumed to be high. HPV is thought to gain access to the basal cell layer and basement membrane through microabrasions of the genital epithelium during sexual contact. Once infected, the basal cells may become a viral reservoir (Stanley, 2010b).

Cervical hrHPV infection generally requires penetrative intercourse. Oral-genital and hand-genital HPV transmission are possible but are much less common than a genital-genital route (Winer, 2003). However, women who have sex with women have rates of HPV positivity, abnormal cervical cytology, and high-grade cervical neoplasia similar to those of heterosexual women, but undergo cervical cancer screening less often. Even women without past sexual experiences with men are at risk for genital HPV and its consequences. This implies that digital, oral, and perhaps object contact places them at risk of hrHPV infection (Marrazzo, 2000; McCune, 2018). Thus, all women and transgender men who retain their uterus should undergo cervical cancer screening according to current guidelines.

Genital HPV detection, including hrHPV, has been reported in apparently sexually naïve girls and young women (Doerfler, 2009; Winer, 2003). Certainly, genital warts that develop in children beyond infancy are always reason to consider the possibility of sexual abuse. However, infection by nonsexual contact, autoinoculation, or fomite transfer appears possible. This is supported by reports of nongenital HPV types in a significant minority of pediatric and adolescent genital wart cases (Cohen, 1990; Obalek, 1990; Siegfried, 1997).

Congenital HPV infection from vertical transmission (mother to fetus/newborn) beyond common, transient skin colonization is rare. Conjunctival, laryngeal, vulvar, or perianal warts that are present at birth or that develop within 1 to 3 years of birth are most likely due to perinatal exposure to maternal HPV (Cohen, 1990). Infection is not linked to presence of maternal genital warts or route of delivery (Silverberg, 2003; Syrjänen, 2010). Accordingly, cesarean delivery is not recommended solely for maternal HPV infection. Exceptions include cases of large genital warts that could obstruct delivery or avulse and bleed with cervical dilation or vaginal delivery.

Infection Outcomes and Natural History

Genital HPV infection causes variable physical outcomes (Fig. 29-6). These can be broadly grouped as latent or expressed

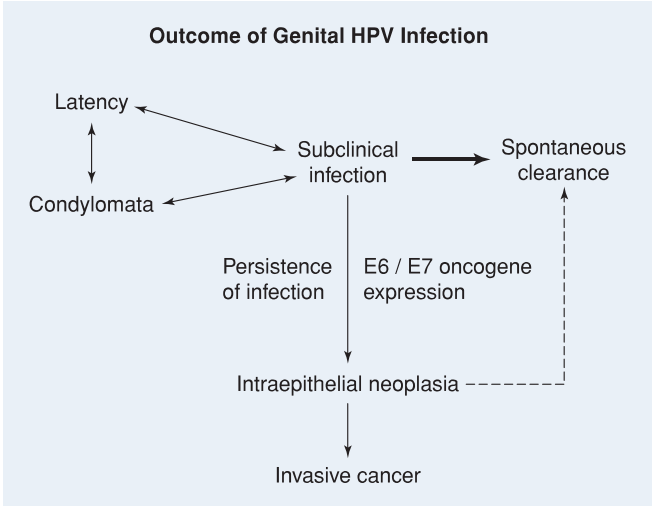

FIGURE 29-6 The natural history of genital human papillomavirus (HPV) infection varies between individuals and over time. Most infections are subclinical. Spontaneous resolution is the most common outcome. Neoplasia is the least common manifestation of HPV infection, and it develops from persistent infection and integration of HPV DNA.

infections. Infection expression may be productive, that is, creating new infectious virus particles, or it may be neoplastic, causing preinvasive disease or malignancy. Temporally, HPV infection can be transient (spontaneous resolution, clearance) or persistent. High-grade neoplasia (CIN 3, AIS, or cancer) is the least common outcome of genital HPV infection and requires HPV expression and persistence.

Latent infection theoretically occurs when cells are infected but HPV remains quiescent. No cellular or tissue effects are evident, as the virus is not actively replicating. However, HPV is present below detectable levels. Thus, it is uncertain whether apparent HPV clearance constitutes true HPV resolution or whether it reflects latency. It may be that both latency and clearance are outcomes of HPV infection. Reappearance of previously resolved HPV-related lesions after loss of immune competence is indirect evidence of latency. Clearance versus permanent immune suppression of HPV manifestations cannot be distinguished using current technology.

Productive infections are characterized by viral life-cycle completion and plentiful production of infectious viral particles (Stanley, 2010a). Viral gene expression and assemblage are completed in synchrony with terminal squamous differentiation and conclude with desquamation of infected squames. These infections have little or no malignant potential because the HPV genome remains episomal, and its oncogenes are expressed at very low levels (Durst, 1985; Stoler, 1996). Productive HPV infections cause either visible genital warts, called *condylomata acuminata*, or, much more commonly, subclinical infections, which are not readily apparent.

Neoplastic infections result in cancer precursor lesions and invasive cancers. The circular HPV genome is disrupted and integrates at random locations into a host chromosome (Fig. 30-1, p. 656). Unrestrained transcription of the *E6* and *E7* oncogenes follows (Durst, 1985; Stoler, 1996). The E6 and E7 oncoproteins produced interfere with the function of

and accelerate degradation of p53 and pRb, respectively. Both are key host tumor-suppressor proteins (Fig. 30-2, p. 656). This leaves infected cells vulnerable to malignant transformation by loss of cell-cycle control, cellular proliferation, and accumulation of DNA mutations over time (Doorbar, 2012).

In resultant preinvasive lesions, normal epithelial differentiation is disrupted and incomplete. The degree of disruption is used to grade LAGT histology as low-grade or high-grade SIL. The average age at diagnosis of low-grade cervical disease is younger than that of high-grade lesions and invasive cancers. Thus, disease was thought to progress from milder- to higher-grade lesions over time. An alternative theory now proposes that low-grade lesions are generally acute, transient, and not oncogenic. High-grade lesions and cancers are likely monoclonal and arise de novo rather than from preexistent low-grade disease (Baseman, 2005; Kiviat, 1996).

Most HPV infection and related lesions, whether clinical or subclinical, spontaneously resolve, especially in adolescents and young women (Ho, 1998; Moscicki, 1998). Whether apparent clearance reflects true resolution of infection or limited testing sensitivity remains unresolved (Winer, 2011). Several studies show that lrHPV infections resolve faster than hrHPV ones (Moscicki, 2004; Schlecht, 2003; Woodman, 2001).

Persistent hrHPV infection is necessary for the development of cervical neoplasia. Few HPV infections become persistent. Most young women (65 percent) with HPV 16/18 infections lasting more than 6 months will develop SIL (Trottier, 2009). The risk of progression to high-grade neoplasia increases with age, as HPV infection in older women is more likely to reflect persistence than serial reinfection (Hildesheim, 1999). Although humoral immunity addresses initial HPV infection, cell-mediated immunity plays the larger role in HPV persistence and in progression or regression of benign and neoplastic lesions.

The pathogenesis of HPV-related neoplasia at other anogenital sites is believed to be similar to that of the cervix. Genital HPV infection is usually multifocal and involves the cervix most often. Neoplasia at one site raises the risk of neoplasia elsewhere in the LAGT (Spitzer, 1989).

Infection Diagnosis

HPV infection is clinically suspected based on lesions or results of cytology, histology, and colposcopy, all of which are subjective and often inaccurate. Serology is unreliable and cannot distinguish past from current infection (Dillner, 1999). As already noted, culture of HPV is not feasible. HPV testing more accurately confirms HPV infection. Clinical HPV testing involves the direct detection of HPV nucleic acids by in situ hybridization, nucleic acid amplification testing (NAAT), polymerase chain reaction (PCR), or other techniques (Molijn, 2005). Currently, four clinical hrHPV tests are approved by the Food and Drug Administration (FDA), and all use NAAT to detect any of 13 or 14 different hrHPV types. Three of these tests can report specifically the presence of HPV 16 or HPV 18 (genotyping) to aid risk stratification. A negative HPV test result does not exclude genital HPV infection because only specific oncogenic HPVs are tested for, and sensitivities are set to detect cervical neoplasia. Therefore, these tests are not approved for routine STD screening. Testing for lrHPV has no routine clinical indication and is discouraged as it can lead to inappropriate expense, evaluation, and treatment.

The clinical role of hrHPV testing for cervical cancer screening and for surveillance of SIL continues to evolve. It is, often in combination with cytology, an important component of cervical cancer screening, management of abnormal screening-test results, and surveillance post-colposcopy and posttreatment. Numerous studies indicate that HPV self-sampling may become a useful strategy to engage more women in cervical cancer screening programs in the future (Yeh, 2019).

Infection Treatment

The indications to treat HPV-related LAGT disease are symptomatic warts, high-grade neoplasia, or invasive cancer. No effective treatment resolves subclinical or latent HPV infection. Harm may result from unrealistic attempts to eradicate HPV infections and LSIL, which are usually self-limited. Encouragement of positive health behaviors and optimal management of immunocompromise seem sensible. Various treatment modalities are available for genital warts and are chosen according to lesion size, location, and number (Rosales, 2014). Mechanical removal or destruction, topical immune modulators, and chemical or thermal coagulation can be used (Table 3-12, p. 73). Examination of a male partner does not benefit a female partner either by influencing reinfection or by altering the clinical course or treatment outcome of her genital warts or LAGT neoplasia (Centers for Disease Control and Prevention, 2010).

Visible lesions caused by HPV lie at either end of the disease spectrum, either condylomata or invasive cancers. They can look very similar. Intraepithelial lesions tend to be invisible to unaided inspection. Therefore, liberal use of biopsy before treatment is prudent. This is especially true for an atypical-appearing genital lesion, a visible cervical lesion, or any LAGT lesion in an immunocompromised or older patient.

Infection Prevention

Behavior

Sexual abstinence, delaying coitarche, and limiting the number of sexual partners are logical strategies to avoid genital HPV infection and its adverse consequences. However, evidence is lacking from trials of counseling and sexual practice modification. Condoms do not cover all anogenital skin and therefore may not be completely protective. However, condoms do appear to reduce acquisition and transmission rates of HPV, even when used inconsistently (Winer, 2003).

Vaccines

Vaccines offer the greatest promise for HPV infection prevention (prophylactic vaccines) and possibly reversal of its sequelae in those already infected (therapeutic vaccines). Although highly effective prophylactic vaccines are used worldwide, development of therapeutic vaccines for HPV-related neoplasias remains experimental at this time.

Both local and humoral immunity are thought to protect against incident HPV infection. Prophylactic vaccines elicit

high levels of type-specific humoral antibody production that prevents new HPV infection by blocking its entry into host cells (Stanley, 2010b). They do not prevent transient HPV positivity or resolve preexistent infection or HPV-related neoplasia. HPV vaccination has the potential to prevent malignancy for at least six body sites that include cervix, vulva, vagina, penis, anal canal, and oropharynx if administered before vaccine-type HPV infection takes place.

Prophylactic HPV vaccines use recombinant technologies for the synthetic production of the L1 capsid proteins of each HPV type included in the vaccine. The resultant virus-like particles are highly immunogenic but not infectious, as they lack any viral DNA (Stanley, 2010b). Seroconversion rates in excess of 99 percent to vaccine viral types are typical.

Only one vaccine is currently available in the United States. Gardasil 9 is a nonavalent HPV vaccine (9vHPV) against HPV types 6, 11, 16, 18, 31, 35, 45, 52, and 58. Coverage for the latter five types was not included in earlier HPV vaccines. HPV types 6 and 11 account for at least 90 percent of genital condylomata and recurrent laryngeal papillomas, and a significant number of low-grade cervical cytologic and colposcopic abnormalities. Types 16 and 18 cause approximately 60 to 70 percent of cervical cancers; a significant number of anal, vulvar, and vaginal cancers; and many preinvasive lesions at all sites. The other five viral types in the vaccine add coverage for an additional 15 to 20 percent of cervical cancers (Petrosky, 2015). Gardasil 9 is FDA approved for the prevention of genital warts and cervical, vulvar, vaginal, and anal neoplasia caused by any of its nine HPV types. In previously uninfected individuals, it protects against at least 96 percent of incident infections and their resultant neoplasia caused by all nine HPV types.

Ideally, vaccination takes place prior to sexual activity initiation, when the potential benefit is greatest. However, a history of prior sexual activity, HPV-related disease, or HPV-test positivity should not deter vaccine administration. Moreover, HPV testing is not recommended prior to vaccination (American College of Obstetricians and Gynecologists, 2017). The Advisory Committee on Immunization Practices (ACIP) currently recommends that HPV vaccine be administered routinely to all girls and boys aged 11 to 12 years (as early as age 9 years) (Meites, 2019). Catch-up vaccination is also recommended for all 13- to 26-year-old persons. The ACIP does not recommend routine catch-up vaccination for persons aged 27 to 45 years due to limited benefit. This is despite recent FDA approval for vaccination in this age group (Food and Drug Administration, 2018). Instead, the ACIP agrees with the American College of Obstetricians and Gynecologists (2019) recommendation of shared decision-making with persons aged 27 to 45 years who have not previously received the HPV vaccine and are at risk of acquiring HPV. Strong, unequivocal advocacy for early HPV vaccination by providers is critical to vaccine uptake and effectiveness. As of 2018, U.S. HPV vaccination rates remain low. Only 51 percent of adolescents aged 13 to 17 years are up to date with the HPV vaccine series (Walker, 2019).

Gardasil 9 is administered as a three-dose series if started at or after age 15 years. The second dose is administered 1 to 2 months after the first, and the third dose is given 6 months after the first. If the vaccination schedule is interrupted for pregnancy or other reasons, the vaccine series is continued as soon as possible with the next dose. The series is not restarted. Prolongation of the dosing schedule does not appear to diminish immunogenicity. If HPV vaccination is initiated before age 15 years, only 2 doses are needed. This is because the vaccine is more immunogenic at an earlier age. The second dose is given 6 to 12 months following the first (Meites, 2016). No data support the need for later booster dosing. Recent evidence suggests that a single dose of HPV vaccine may result in sufficient and enduring protection against HPV infection and neoplasia, and future dosing recommendations may be modified (Brotherton, 2019; Kreimer, 2018).

Vaccination that was begun with earlier two-valent (2vHPV) and four-valent HPV (4vHPV) vaccine formulations can be continued using 9vHPV. The series is not restarted. After completion of a 2vHPV or 4vHPV vaccine series, there is no ACIP recommendation for administration of 9vHPV to extend HPV coverage. The additional HPV types included in the 9vHPV vaccine mostly target cancers in women (Meites, 2016).

HPV vaccines have excellent safety profiles, are well-tolerated, and can be administered along with other recommended vaccinations. Injection-site erythema, pain, and swelling are common. These can increase in severity following subsequent doses but are usually mild to moderate. HPV vaccination is avoided during pregnancy, but pregnancy testing is not recommended prior to administration (American College of Obstetricians and Gynecologists, 2017). If inadvertently given during pregnancy, no action is needed. Vaccination can be given during lactation. Immunocompromised persons are candidates to receive the vaccine and show high seroconversion rates despite concerns for a blunted immune response. 9vHPV should be given with caution to persons who experienced an allergic reaction to a prior dose, have an allergy to yeast, or have had a recent febrile illness.

HPV vaccination prevents most, but not all, HPV-related cancers, and therefore cervical cancer screening should continue per current guidelines. Countries with high vaccination rates have dramatically lowered HPV 16 and 18 prevalence and reduced rates of anogenital warts and high-grade cervical neoplasia (Drolet, 2019). Despite suboptimal HPV vaccination rates in the United States, infections involving the HPV types in the 4vHPV (HPVs 6, 11, 16, and 18) have decreased sharply since vaccine introduction. HPV 16 and 18 prevalence has declined from 9 percent to 5.5 percent in the general population of women (Hirth, 2019). The decreased prevalence in both vaccinated and unvaccinated adolescents and women is evidence of both direct and herd immunity as a result of HPV vaccination (Markowitz, 2019). A significant drop in the diagnosis of high-grade cervical disease, including AIS, has already been observed in U.S. women aged 18 to 24 (Cleveland, 2019; McClung, 2019).

CERVICAL INTRAEPITHELIAL NEOPLASIA

Risk Factors

An estimated 412,000 cases of CIN are diagnosed in the United States annually (Henk, 2010). Similar to invasive cervical cancer, CIN is most strongly related to persistent genital

TABLE 29-1. Risk Factors for Cervical Neoplasia

Demographic risk factors
Ethnicity (Latin American countries, U.S. minorities)
Low socioeconomic status
Increasing age
Behavioral risk factors
Early coitarche

Exogenous hormones (combination hormonal contraceptives)
Parity
Immunosuppression
Inadequate screening

hrHPV infection and aging (Table 29-1) (Ho, 1995; Kjaer, 2002; Remmink, 1995).

The median age of cervical cancer diagnosis in the United States (late fifth decade) is approximately a decade later than for CIN. In an older woman, HPV infection is more likely to persist than resolve. Aging is linked to waning immune competence and allows the accumulation of genetic mutations that can lead to malignant transformation. Additionally, adverse socioeconomic factors and decreased need for prenatal care or contraception cause older women to be screened less often.

Behavioral risk factors for CIN mirror those for HPV acquisition and include early sexual activity, multiple partners, and male partner promiscuity (Buckley, 1981; de Vet, 1994; Kjaer, 1991). After adjustments for HPV positivity and lower socioeconomic status, tobacco use also raises CIN risk (Castle, 2004; Plummer, 2003).

Combination oral contraceptives (COCs) have been linked to a higher risk of CIN and cervical cancer in current users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007; Roura, 2016). Possible mechanisms include increased persistence of HPV infection and oncogene expression (de Villiers, 2003). In contrast, multiple studies have not found a greater CIN risk in users of hormonal contraceptives or postmenopausal hormone therapy (Castle, 2005; Harris, 2009; Yasmeen, 2006). In addition to a known increased risk of cervical and vaginal clear cell adenocarcinoma, DES exposure in utero appears to raise the risk of developing cervical HSIL (Hoover, 2011). However, this greater HSIL risk may be the result of higher screening rates in these women (Verloop, 2017).

Increasing parity has been correlated with cervical cancer risk, but it is unclear if this is related to earlier sexual activity, a progestin-exposure effect, or other factors. Immune suppression during pregnancy, hormonal influences on cervical epithelium, and physical trauma related to vaginal deliveries have all been suggested (Brinton, 1989; Muñoz, 2002; Roura, 2016).

Immunocompromised women in general have increased risks for CIN and for greater lesion severity, multifocal lesion patterns, and multisite LAGT disease. They also experience higher rates of treatment failure, persistence, and LAGT disease recurrence compared with those who are immune competent. Specifically, women with human immunodeficiency virus (HIV) infection have higher rates of abnormal cervical cytology and CIN compared with women without HIV. Transplant recipients have an increased risk of developing malignancy after transplantation, including neoplasms of the LAGT and anal canal (Gomez-Lobo, 2009). Women taking immune suppressive medications for other disorders show higher rates of LAGT neoplasia.

Inadequate screening is a strong cervical neoplasia risk factor. Of women with cervical cancer in the United States, approximately 50 percent had never been screened and 10 percent had not been screened during the 5 years prior to diagnosis (American College of Obstetricians and Gynecologists, 2018a). Lack of screening is a major contributor to elevated rates of cervical cancer in socioeconomically disadvantaged women (Benard, 2007).

Natural History

Preinvasive lesions can spontaneously regress, remain stable, or progress. The risk of progression to invasive cancer rises with CIN severity. Estimated rates of CIN progression, persistence, and regression are shown in Table 29-2 (Ostor, 1993). Low-grade lesions are thought to be manifestations of acute HPV infection, and approximately 90 percent regress within a few years. High-grade lesions are less likely to regress. Approximately 40 percent of CIN 2 cases show spontaneous regression within 2 years. This is even more frequent (>60 percent) in young, healthy women (Castle, 2009b; Moscicki, 2010). CIN 2 is thought to be a mixture of low- and high-grade lesions that are difficult to distinguish histologically, rather than an intermediate step in the progression from CIN 1 to CIN 3. The risk of progression of biopsied but untreated CIN 3 to invasive cancer approximates 30 percent over 30 years (McCredie, 2008).

TABLE 29-2. Natural History of Cervical Intraepithelial Neoplasia (CIN) Lesions

	Regression (%)	Persistence (%)	Progression to CIS (%)	Progression to Invasion (%)
CIN 1	57	32	11	1
CIN 2	43	35	22	5
CIN 3	32	<56	–	>12

CIS = carcinoma in situ.

CERVICAL INTRAEPITHELIAL NEOPLASIA DIAGNOSIS

In general, LAGT preinvasive lesions are visible only with aided inspection. The exception is high-grade VIN, which is often visible, palpable, or both. Only cervical lesions at either end of the neoplastic disease spectrum are grossly visible, namely, condylomata and invasive cancers. Accordingly, grossly visible cervical lesions require prompt biopsy.

The goal of cervical cancer screening is to identify preinvasive lesions (CIN) or early-stage cervical cancer that can be treated most successfully. Abnormal test results lead to further management with repeat cytology, HPV testing, or colposcopy with biopsy of lesions. Screening previously was limited to cervical cytology. HPV testing has become an important screening tool either paired with cytology (*co-testing*) or, recently, as a stand-alone screening test.

Cervical Cytology

Cervical cytologic screening is one of modern medicine's great success stories (Koss, 1989). The Papanicolaou (Pap) test has never been evaluated in a randomized or controlled, prospective trial. Nonetheless, countries with organized screening programs have consistently realized dramatic declines in cervical disease. Widespread use of the Pap test since the 1950s has reduced the incidence of and mortality from invasive cervical cancer by more than 80 percent in the United States (Howlader, 2017). Approximately 7 percent of U.S. women who undergo Pap testing will have an abnormal result (Wright, 2012).

The Pap test's specificity is consistently high and approximates 98 percent. However, estimates of its sensitivity for detection of CIN 2 or worse are lower and variable, ranging from 45 to 65 percent (Whitlock, 2011). This limited sensitivity is countered by repetitive screening throughout a woman's life. Although the incidence of cervical squamous carcinoma has declined due to Pap testing, the relative and absolute incidences of cervical adenocarcinoma have increased, particularly in women younger than 50 (Herzog, 2007). Adenocarcinoma and adenosquamous carcinoma now account for at least 20 percent of cervical cancers. This rise may partly stem from the Pap test's lower sensitivity for the detection of adenocarcinoma than for squamous cancers and their precursor lesions.

False-negative Pap test results may derive from sampling errors that fail to collect abnormal cells or from screening errors where the screener overlooks or misclassifies abnormal cells (Wilkinson, 1990). Mandated quality-assurance measures and computerized slide-screening technologies can help address screening errors. Suboptimal management of abnormal results by providers and poor patient compliance also contribute to avoidable cases of cervical cancer.

Optimizing the Pap Test

Ideally, Pap tests are scheduled to avoid menstruation. Patients should abstain from vaginal intercourse, douching, vaginal tampon use, and intravaginal medicinal or contraceptive creams for a minimum of 24 to 48 hours before tested. Treatment of cervicitis or vaginitis prior to Pap testing is optimal. However, Pap testing is not deferred due to suboptimal conditions if the patient may not return. This is especially true in patients with unexplained discharge or unscheduled bleeding, as these may be signs of LAGT cancer.

As shown in Figure 22-12 (p. 497), cervical squamous cell appearance varies throughout the menstrual cycle and with hormonal status. Thus, clinical information added to pathology requisition forms aids accurate cytology interpretation. Data include date of last menstrual period, pregnancy or menopausal status, exogenous hormone use, abnormal bleeding, and prior abnormal Pap test findings, CIN, or other LAGT neoplasia. Intrauterine devices (IUDs) also can cause reactive cellular changes and are noted.

Full visualization of the cervix is essential to detect gross lesions and collect adequate specimens. Speculum placement should be as comfortable as possible. A thin coating of water-based lubricant can be smeared on the outside of the speculum blades without compromising Pap test quality or interpretation (Griffith, 2005; Harmanli, 2010). Touching the cervix prior to performing Pap testing is avoided, as dysplastic epithelium may be inadvertently removed by minimal trauma. Discharge covering the cervix may be carefully absorbed by a large swab without contacting the cervix. Vigorous blotting or rubbing can theoretically cause scant cellularity or a false-negative Pap test result. When indicated, additional cervical sampling to detect infection should follow Pap test collection.

Sampling of the transformation zone at the SCJ adds substantial sensitivity of the Pap test. Techniques are adapted and sampling devices are chosen according to SCJ location, which varies widely with age, prior obstetric laceration, and hormonal status. Women with known or suspected in utero DES exposure also may benefit from a separate Pap test of the upper vagina, because of their increased vaginal cancer risk (Chap. 32, p. 695).

Cytology Collection

Three types of plastic devices are commonly used to sample the cervix: the spatula, broom, and endocervical brush (cytobrush) (Fig. 29-7). A spatula predominantly samples the ectocervix. An endocervical brush samples the endocervical canal and is used in combination with a spatula. A broom samples both endo- and ectocervical epithelia simultaneously but can be supplemented by an endocervical brush. Wooden collection devices and cotton swabs are no longer recommended due to their inferior collection and release of cells.

A cervical Ayers spatula with its saddle-shaped end is positioned to best fit the ectocervical contour, straddle the SCJ, and sample the distal endocervical canal. It firmly scrapes the cervical surface while completing at least one full rotation. After the spatula sample is obtained, the endocervical brush is inserted into the endocervical canal until the outermost bristles remain visible just within the external os. This prevents inadvertent sampling of lower uterine segment cells, which can mimic atypical cervical cells. To minimize bleeding, the brush is used after the ectocervix has been sampled and is rotated only one-quarter to one-half turn. If the cervical canal is very wide, the brush can be directed around the canal perimeter to contact all surfaces.

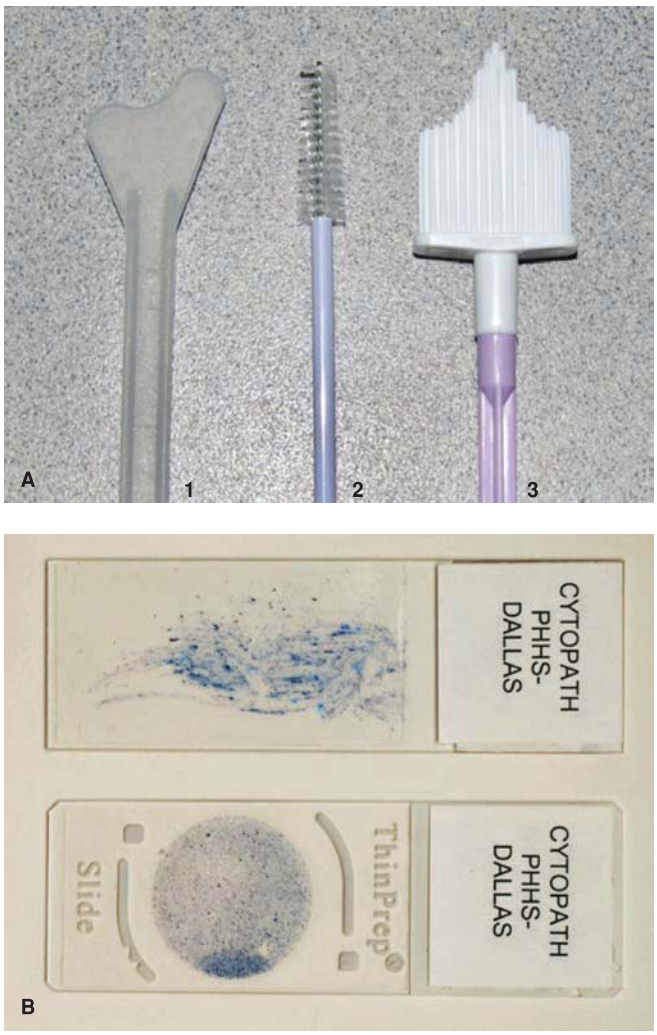

FIGURE 29-7 A. Cervical cytology collection devices: (1) Plastic spatula. (2) Endocervical brush. (3) Plastic broom. **B.** Pap test preparations. Conventional cervical cytology is prepared by smearing collected cells directly onto a glass slide with the collection device followed by immediate fixation (*upper slide*). Liquid-based cytology involves transfer of collected cells from the collection device into a liquid transport medium with subsequent processing and transfer onto a glass slide. Cells are distributed over a smaller area, and debris, mucus, blood, and cell overlap are largely eliminated (*lower slide*). (Reproduced with permission from Dr. Raheela Ashfaq.)

Broom devices have longer central bristles that are inserted into the endocervical canal and collect cells there. These long bristles are flanked by shorter ones that splay out over the ectocervix with gentle pressure during rotation. Five rotations in the same direction are recommended. Reversing direction may release and lose cellular material. Broom devices are favored for liquid-based Pap testing.

To submit collected cells to the laboratory, conventional glass slides (*Pap smear*) and liquid-based Pap tests are considered equally acceptable by all current guidelines (American College of Obstetricians and Gynecologists, 2018a; Saslow, 2012; U.S. Preventive Services Task Force, 2018).

Conventional slide preparation requires special care to avoid air drying artifact to protect slide quality. The spatula or broom sample is held, while the endocervical brush sampling immediately follows. The spatula or broom sample is then quickly spread as evenly as possible over one half to two thirds of a glass slide (see Fig. 29-7). The endocervical brush is firmly rolled over the remaining area of the slide, after which an appropriate fixative is quickly sprayed onto the slide from a distance of 10 to 12 inches or by immersing the slide completely in a container of appropriate fixative.

Currently, most cervical cytology specimens are collected into liquid-based media. Two liquid-based cytology (LBC) Pap tests are FDA approved. Sampling and cell transfer to a liquid medium is performed according to manufacturer specifications. SurePath allows for the use of all three device types but uses modified tips that are broken off and sent to the laboratory in the liquid medium. ThinPrep requires the collection device(s) to be repetitively pressed against the medium-container walls to release cells, then vigorously agitated within the medium, and finally discarded.

HPV Testing

HPV testing in clinical practice tests only for 13 or 14 hrHPV types. It has several indications that include cervical cancer screening, triage of lesser cytologic abnormalities to later repeat testing or immediate colposcopy, surveillance after colposcopy, or surveillance after treatment. Until recently, its use for primary cervical cancer screening was restricted to co-testing, which is a Pap test plus HPV test. However, HPV testing alone for cervical cancer screening now has approval from one oversight agency (U.S. Preventive Services task Force, 2018).

A role for HPV testing in cervical cancer screening is attractive because of its greater immediate sensitivity for CIN 3 or cervical cancer and the objectivity of its results. However, screening guidelines incorporating HPV testing must compensate for a lower specificity, particularly in young women, described in the next section.

HPV testing is usually performed from the residual LBC Pap medium after the cytology slide is prepared. Alternatively, a cervical sample for HPV can be obtained separately in a specific collection device. As noted earlier, there is no clinical role for testing for lrHPV types (p. 625) (Castle, 2014; Thomsen, 2014).

Co-testing

The combination of HPV testing with cytology (co-testing) raises the sensitivity of a single screening test for high-grade neoplasia and leads to earlier detection and management of HSIL (Ronco, 2014). The lack of sensitivity with cytology alone for cervical adenocarcinoma and its rising incidence both support HPV testing for primary screening (Castellsagué, 2006). This strategy is not recommended by current guidelines for women younger than 30 because of the high prevalence of HPV infection in this age group and the resultant lack of test specificity.

Co-testing offers a nearly 100-percent negative predictive value for high-grade neoplasia. Because of this, coupled with the slow progression of new HPV infection to high-grade neoplasia or cancer and increased cost, co-testing is repeated at 5-year intervals if both cytology and HPV test findings are negative. If cytologic results are abnormal, current

cytologic-management guidelines are followed (p. 632). Cytology-negative and HPV-positive test results will occur in <10 percent of screened patients (Castle, 2009a; Datta, 2008). In such cases, co-testing is repeated 12 months later. Colposcopy is recommended for recurrent, positive HPV results or an abnormal repeat cytology.

An alternative strategy is now available for the management of normal cytologic findings but a positive HPV result. A reflex test specifically for HPVs 16 and 18, (genotyping) can be performed in many settings. If HPV 16 or 18 is found, immediate colposcopy is recommended (American College of Obstetricians and Gynecologists, 2018a; Saslow, 2012). This approach identifies those at highest risk for significant disease and shortens time to diagnosis (Khan, 2005; Wright, 2015).

Primary HPV Testing

Sufficient evidence supports HPV testing alone (without cytology) as an option for primary cervical cancer screening (Castle, 2011; Cuzick, 2006; Dillner, 2013, Ronco, 2014). HPV testing alone is approximately twice as sensitive (>90 percent) as a single Pap test and leads to earlier detection of high-grade disease. The very high negative predictive value of a single HPV test result is clinically reassuring that high-grade disease or cancer is not present. Recent evaluations show that co-testing does not perform better than HPV testing alone but adds expense (Schiffman, 2018). Specificity declines with HPV testing alone, particularly in younger women (Mayrand, 2007; Ronco, 2006, 2010). This could lead to excessive numbers of colposcopies, biopsies, and treatments of lesions that could have spontaneously regressed. Genotyping is part of primary HPV screening for cervical disease and allows the triage of women who test positive for HPV 16 or 18 to immediate colposcopy. Those with test results indicating no HPV 16 and 18 but identifying other hrHPVs receive follow-up other than immediate colposcopy. This strategy attempts to counter the lower specificity of HPV testing. In sum, primary HPV testing is expected to result in more colposcopic referrals initially but yield higher and earlier HSIL detection rates. As of 2019, two HPV tests, both providing genotyping, were approved by the FDA for primary cervical cancer screening in women aged ≥25 years. This represents a major paradigm shift in cervical cancer screening, in that Pap testing assumes a secondary role. To date, one oversight agency has approved HPV testing alone for primary cervical cancer screening in women at least 30 years old (U.S. Preventive Services Task Force, 2018). Others are expected to as well in the near future.

Interim guidelines for managing the results of primary HPV screening are published and are expected to be revised in coming years (Huh, 2015; Wentzensen, 2019). Immediate colposcopy is recommended if HPV 16 or 18 is identified. If other HPV types are found, triage to reflex cytology is proposed. Colposcopy is recommended for any cytologic abnormalities, as per current management guidelines. However, management of HPV-positive, non-HPV 16 or 18 results is not yet firmly established. Interim recommendations for reflex cytology may be replaced by other, more predictive triage tests such as p16/Ki-67 dual staining or methylation markers (Dick, 2019; Wentzensen, 2019).

Current Cervical Cancer Screening Guidelines

Perspectives on Guidelines

All currently approved cervical cancer screening strategies, including cytology, co-testing, and primary HPV testing, dramatically reduce an individual's lifetime risk of cervical cancer. The choice of screening strategy should be a shared decision by the provider and patient. The balance of benefits, harms, and cost-effectiveness of each screening strategy merits careful consideration by both providers and health-care policy agencies (National Cancer Institute, 2019a; U.S. Preventive Services Task Force, 2018). Evidence-based cervical cancer screening recommendations continue to evolve. All major guidelines are similar and only pertain to average-risk women, namely, immune competent women without prior HSIL, cervical cancer, or in utero DES exposure (American College of Obstetricians and Gynecologists, 2018a; Saslow, 2012; U.S. Preventive Services Task Force, 2018). All recognize the acceptability of both conventional and liquid-based cytology, the age for screening initiation and cessation, screening intervals, and continued standard screening after HPV vaccination. Importantly, patient adherence to screening guidelines or needed follow-up of abnormalities should not impede other indicated gynecologic care, especially the provision of contraception.

Screening Initiation

Cervical cancer screening begins at age 21 in average-risk women. This is true regardless of sexual history, sexual orientation, or other risk factors. In young women, most Pap test result abnormalities represent transient HPV infection, and the spontaneous regression of even high-grade lesions is common (Moscicki, 2005). Cervical cancer is rare in adolescents and less preventable by screening (Saslow, 2012). Additionally, treatment of high-grade CIN in adolescents is often followed by persistent Pap test result abnormalities and may have adverse reproductive consequences (Case, 2006; Moore, 2007).

Screening Strategies and Intervals

For women aged 21 to 29 years, all current guidelines recommend screening with cytology alone at 3-year intervals. Co-testing or primary HPV screening is not used. Women aged 30 to 65 years can continue screening with cytology alone at 3-year intervals or can begin co-testing at 5-year intervals. The American Cancer Society, American Society for Colposcopy and Cervical Pathology (ASCCP), American Society for Clinical Pathology, and American College of Obstetricians and Gynecologists (2018a) deem co-testing preferable to cytology alone in women ≥30 years (Saslow, 2012). The U.S. Preventive Services Task Force (2018) now endorses cytology alone every 3 years, co-testing every 5 years, and HPV testing alone every 5 years as equivalent, acceptable screening strategies for women aged ≥30 years or more. Co-testing and primary hrHPV testing are advantageous for individuals who desire a longer screening interval. Regardless of strategy, screening more frequently than recommended adds cost, does not significantly lower cervical cancer risk, and exposes patients to the harms of overdiagnosis and overtreatment.

Screening Discontinuation

Screening may be stopped at age 65 years in those at average risk for cervical cancer and who have undergone adequate screening, regardless of past or current sexual history. Adequate screening is defined as three consecutive, negative cytology results or two consecutive, negative co-test results in the prior 10 years, with the most recent result occurring within the past 5 years. Women with prior treatment for CIN 2, CIN 3, AIS, or cervical cancer should continue screening for at least 20 years past their diagnosis and treatment, even if this extends screening beyond age 65. These women carry increased long-term risks for cervical cancer (American College of Obstetrics and Gynecology, 2018b; Saslow, 2012; U.S. Preventive Services Task Force, 2018). Screening cessation can be considered at any age if life expectancy becomes limited to the point where the development of cervical cancer becomes unlikely.

Posthysterectomy

Primary vaginal carcinoma is rare and makes up <5 percent of all gynecologic malignancies (Siegel, 2019). All guidelines recommend against Pap test screening for women who have undergone total hysterectomy (cervix removed) for a benign-disease indication and who lack a prior high-grade CIN or cervical cancer diagnosis. The absence of a cervix should be confirmed by examination or pathology report, as many women are inaccurate in their personal reporting of hysterectomy type. Women who have undergone supracervical hysterectomy should continue routine screening. Recommendations for vaginal cytology after total hysterectomy in women with prior high-grade cervical neoplasia or cancer are less clear. Vaginal cancer is still rare in these individuals, and screening offers uncertain benefit (Saslow, 2012). The American College of Obstetricians and Gynecologists (2018b) recommends Pap testing of the vaginal cuff every 3 years for 20 years after initial posttreatment surveillance, which is traditionally a schedule of three Pap tests in the first 2 years posthysterectomy.

Vaginal cuff cytology should be collected such that the chosen collection device makes optimal contact with the upper vaginal walls. A plastic spatula or its handle end may be best suited for this. The cuff is sampled with gentle but firm pressure, drawing the device across it several times in the same direction so as not to lose cells. Deep indentations in the vaginal cuff can be sampled with an endocervical brush, and these cells are added to the transport medium. The role of HPV testing for women without a cervix is not defined or generally recommended. HPV testing is FDA approved for cervical testing only. Despite this, vaginal cuff HPV testing is common (Chappell, 2010).

Guidance for the management of vaginal cytology and HPV test results has been suggested based on only limited data (Khan, 2016). HSIL cytology or LSIL and ASC-US that are positive for HPV 16 or 18 should prompt vaginal colposcopy. Non-16/18 positive HPV test results wtih negative, ASC-US, or LSIL cytology can be followed for 2 years without colposcopy. Testing should be repeated in a year; this can be done with a co-test. Vaginal colposcopy is considered if positive HPV testing or abnormal cytology persist.

Immunocompromised Patients

Immunocompromised patients, particularly those with HIV infection and solid organ transplants, are at much greater risk of HPV-related disease, often multifocal, than the general population. As reviewed by the Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents (2019), those with HIV infection have a higher risk of HPV infection and persistence, and therefore of condylomata, preinvasive disease, and cancers of the cervix, vulva, vagina, and anal canal. This risk, particularly of cervical and anal cancer, correlates with the degree of immune compromise. Due to the higher risk and poorer prognosis of cervical cancer in women with HIV infection, it was designated as an acquired immune deficiency syndrome (AIDS)-defining illness. Fortunately, women with HIV infection who receive regular screening and recommended follow-up for CIN experience the same incidence of invasive cervical cancer as women without HIV infection (Massad, 2009). Unfortunately, women with HIV infection have lower compliance rates for screening and follow-up of abnormal results, which compound their already higher risk of LAGT neoplasia (Barnes, 2018).

With HIV infection, screening should commence within 1 year of sexual activity onset and no later than age 21 years. Women aged 21 to 29 years should receive Pap testing at the time of HIV diagnosis (American College of Obstetrics and Gynecology, 2018a; Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents, 2019). If an initial Pap test result is negative, testing should be repeated 6 or 12 months later and then continued every 12 months. After three consecutive, negative Pap test results, the interval of Pap testing can be extended to 3 years. For women aged ≥30 years, cytology screening can be followed as just described, or co-testing every 3 years can begin. This co-testing interval is shorter than for immune competent women. Cervical cancer screening is continued indefinitely even in those aged 65 years or older who have been adequately screened. After hysterectomy for benign disease, vaginal cuff cytology is not recommended. Those with prior high-grade cervical neoplasia or cancer should have annual vaginal cuff cytology. If the history of cervical disease preceding hysterectomy is unclear, women with HIV infection should have continued vaginal cuff cytology screening at intervals similar to cervical screening. This is because CIN is the most common indication for hysterectomy in women with HIV.

The Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents (2019) recommends careful assessment of the entire LAGT with at least visual inspection as part of every routine screening examination. If cervical or vulvar lesions are found, vaginal colposcopy is indicated. No current consensus guides screening for anal cancer in persons with HIV infection. Patients should be questioned regarding anorectal pain or bleeding. A digital examination of the anal canal to detect masses is recommended routinely. Anal cytology testing is discouraged unless referral to centers that offer high-resolution anoscopy is available to address abnormal results.

For other groups of immunocompromised persons without HIV infection, guidelines have been proposed (Chin-Hong, 2019; Moscicki, 2019). The screening recommendations for women with HIV infection are extended to those with solid

organ and stem-cell transplants, inflammatory bowel disease or rheumatoid arthritis treated with immune suppressants, or systemic lupus erythematosus whether or not immune suppressants are used. Solid organ transplant recipients remain at high risk of developing high-grade LAGT lesions and cancers. It is suggested they undergo thorough LAGT examinations annually (Thimm, 2019). Women with diabetes mellitus or those with rheumatoid arthritis or inflammatory bowel disease not treated with immune suppressants can be screened according to guidelines for average-risk women.

The Bethesda System

Cervical cytology reporting is standardized by the Bethesda System nomenclature. Clinically, the key elements reported are specimen adequacy and epithelial cell abnormalities Tables 29-3 and 29-4 (National Cancer Institute Workshop, 1989; Nayar, 2015; Solomon, 2002). Evidence-based recommendations from national organizations guide initial management of cervical cytology abnormalities for nonpregnant women (American College of Obstetricians and Gynecologists, 2018b; Massad, 2013). Guidelines cannot prevent all cervical cancers. Moreover, recommendations cannot address all clinical situations and individualized management is essential. Updated, risk-based guidelines for the management of cytologic abnormalities and histologic CIN and AIS will be published in 2020 by the ASCCP. These will offer more customized management of individual patients depending on their past and current results (Castle, 2019; Demarco, 2017).

TABLE 29-3. The 2014 Bethesda System Cytology Report Components

Specimen Type
Conventional (Pap smear)
Liquid-based (Pap test)
Other

Specimen Adequacy
Satisfactory for evaluation
Unsatisfactory for evaluation (reason specified)

General Categorization (optional)
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormality (see Table 29-4)
Other (see Interpretation/Results)

Interpretation/Results
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormalities (see Table 29-4)
Non-neoplastic findings (optional)
- Cellular variations (atrophy, keratosis, metaplasia)
- Reactive cellular changes (inflammation, repair, radiation)
- Glandular cells status posthysterectomy

Organisms
- *Trichomonas vaginalis*
- Fungal organisms consistent with *Candida* spp.
- Shift in flora suggestive of bacterial vaginosis
- Cellular changes consistent with herpes simplex virus
- Cellular changes consistent with cytomegalovirus
- Bacteria consistent with *Actinomyces* spp.
- Other nonneoplastic findings (optional)

Other
- Endometrial cells in a woman ≥45 years of age
- Other malignant neoplasms (specified)

Adjunctive Testing

Computer-Assisted Interpretation

Educational Notes and Comments (optional)

TABLE 29-4. The 2014 Bethesda System: Epithelial Cell Abnormalities

Squamous cell
Atypical squamous cells (ASC):
- of undetermined significance (ASC-US)
- cannot exclude HSIL (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL)
High-grade squamous intraepithelial lesion (HSIL)
Squamous cell carcinoma

Glandular cell
Atypical:
- Endocervical cells, endometrial cells, glandular cells (AGC)

Atypical, favor neoplastic:
- Endocervical, glandular (AGC)

Endocervical adenocarcinoma in situ (AIS)
Adenocarcinoma
Endocervical, endometrial, extrauterine, not otherwise specified

Specimen Adequacy

This is reported as *satisfactory* or *unsatisfactory* for evaluation and is based on slide cellularity and the presence of obscuring blood or inflammation. The presence or absence of TZ components, that is, endocervical cells and/or presence of squamous metaplastic cells, also is reported. A TZ component is not required for test adequacy. Although its presence is associated with increased detection of cytologic abnormalities, its absence is not associated with failure to diagnose CIN. Pap tests lacking TZ components are repeated in 3 years. For women aged ≥30 years, subsequent HPV testing is preferred and further testing is guided by results.

Unsatisfactory Pap testing samples are unreliable for the detection of cervical neoplasia and also for HPV by some tests. These samples are repeated in 2 to 4 months. If atrophy or a specific cervical or vaginal infection is present, treatment before repeat cytology may be helpful. If the sample is unsatisfactory again, colposcopy is recommended. Rarely, obscuring blood or inflammation on cervical cytology sample indicates invasive cancer. Therefore, unexplained vaginal discharge, abnormal bleeding, or abnormal physical findings should prompt immediate evaluation rather than waiting for repeat cytology or HPV results.

Epithelial Cell Abnormality Management

A cytology report interprets a screening test and does not provide a final diagnosis. Instead, a final diagnosis is determined

subsequently by colposcopy and directed biopsies, as indicated. Pap tests are interpreted as either being negative for intraepithelial lesion or malignancy (NILM) or as demonstrating one or more epithelial cell abnormalities.

Atypical Squamous Cells of Undetermined Significance. The most common cytologic abnormality is *atypical squamous cells of undetermined significance (ASC-US)*. It indicates cells suggesting but not fulfilling all the cytologic criteria for SIL. An ASC-US result often precedes the diagnosis of CIN 2 or 3, but this risk approximates only 5 to 10 percent. Cancer is found in only 1 to 2 cases per thousand (Solomon, 2002).

Management of ASC-US depends largely upon age, HPV status, and prior screening test results. If co-testing is not requested, reflex HPV testing is usually done. *Reflex HPV testing* refers to preordered HPV testing that is triggered only by specific cytology result and is not performed if cytology is negative. Approximately half of reported ASC-US cases will test positive for HPV. The combination of ASC-US cytology and positive HPV testing carries a risk profile similar to LSIL. Therefore, those with ASC-US cytology and positive HPV test results are referred for colposcopy. ASC-US cytology with negative HPV testing is followed up with a repeat co-test in 3 years. ASC-US without HPV testing calls for repeat cytology in 1 year and colposcopy if any abnormal result is obtained.

Low-Grade Squamous Intraepithelial Lesion. LSIL encompasses the cytologic features of HPV infection and CIN 1 but carries a 10- to 15-percent risk of CIN 2 or worse. This risk is similar to the risk associated with ASC-US cytology with positive HPV test results. More than 80 percent of LSIL cases will test positive for HPV, and thus reflex HPV testing is usually not helpful. Colposcopy is generally indicated for LSIL cytology. Similar to ASC-US cytology, individualized management of LSIL is influenced by age, current HPV status if known, and past screening results.

Atypical Squamous Cells, Cannot Exclude HSIL. Five to 10 percent of atypical squamous cell cases are designated as *atypical squamous cells, cannot exclude HSIL (ASC-H)*. This finding should not be confused with ASC-US. ASC-H describes cellular changes that do not fulfill criteria for HSIL cytology, but an underlying high-grade lesion cannot be excluded. Histologic HSIL is found in up to 25 percent of ASC-H cases, and this rate is higher than associated with ASC-US or LSIL. Thus, colposcopy is indicated regardless of age or HPV test result. Similar to LSIL, reflex HPV testing is not helpful due to a high rate of HPV positivity. If the SCJ is not fully visualized during colposcopy, a diagnostic excision procedure is recommended unless initial biopsies show invasive cancer.

High-Grade Squamous Intraepithelial Lesion. HSIL encompasses cytologic features suggesting CIN 2 and CIN 3 (Fig. 29-8). It carries a high risk of underlying histologic HSIL (at least 70 percent) or invasive cancer (1 to 2 percent) (Kinney, 1998). Colposcopic evaluation is therefore warranted regardless of age or HPV status. Alternatively, immediate excision is acceptable in some nonpregnant patients depending on other factors such as age and concerns regarding future pregnancy.

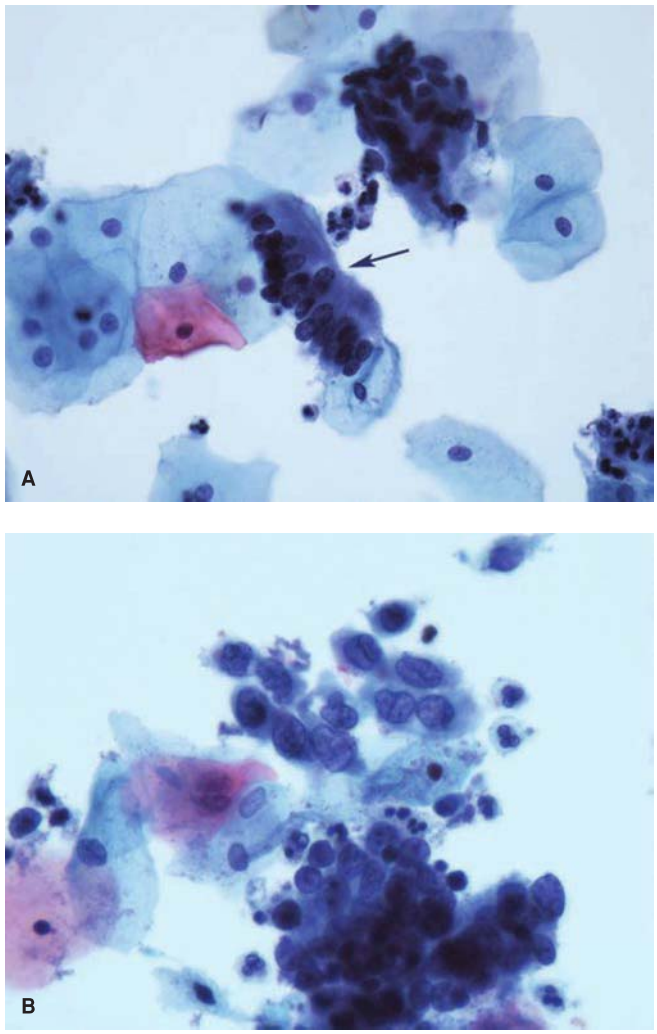

FIGURE 29-8 A. Normal Pap test findings. A fragment of benign columnar mucinous endocervical epithelium is seen (*arrow*). The endocervical cells are viewed from the side in this fragment, imparting a "picket fence" appearance. Normal squamous cells representative of the superficial epithelial layer (eosinophilic-staining cell) and intermediate cell layer (basophilic-staining cells) lie in the background. **B.** Pap smear showing a high-grade squamous intraepithelial lesion (HSIL). The dysplastic squamous cells have nuclear membrane irregularities and a high nucleus-to-cytoplasm ratio, reflecting cytologic immaturity. The greater ratio in some of these cells would classify this as severe cervical intraepithelial neoplasia (CIN 3). (Reproduced with permission from Dr. Kelley Carrick.)

This latter strategy is reasonable since colposcopy may miss small high-grade lesions, and most cases of HSIL cytology eventually result in excision for diagnosis or treatment. As with ASC-H, if the SCJ is not fully visualized during colposcopy, a diagnostic excision procedure is recommended unless initial biopsies show invasive cancer.

Glandular Cell Abnormalities. This group includes atypical glandular cells (AGC), atypical endocervical cells, and atypical endometrial cells; atypical glandular or endocervical cells, favor neoplastic; and endocervical AIS. Similar to HSIL, this category carries a high risk of neoplasia. Adenocarcinoma cytology can be designated as endocervical, endometrial, or extrauterine.

Paradoxically, squamous neoplasia is more frequently diagnosed than glandular disease following cytology that reports AGC or atypical endocervical cells (Schnatz, 2006). The risk of endometrial and other reproductive tract cancers and risk of cancers at other sites such as breast, ovary, and colon are also elevated. In one large review of cytology results with AGC, at least CIN 2 or AIS was subsequently diagnosed in nearly 20 percent; cervical cancer, in 4 percent; and extracervical cancers, in 4 percent (Verdoodt, 2016). In this study, a concurrent negative HPV test result increased risk of extracervical disease diagnosis. Specifically, extracervical malignancy was diagnosed in 18 percent of those who were aged ≥50 years and had negative HPV test results.

Accordingly, initial evaluation of a cytologic glandular cell abnormality includes colposcopy and endocervical sampling, regardless of HPV status. It also includes endometrial sampling in patients aged ≥35 years or in younger women with risk factors for endometrial disease (Chap. 8, p. 183). If atypical endometrial cells are specified in the cytology report, initial endometrial and endocervical sampling are acceptable. These are followed by colposcopy, if initial sampling results are negative.

Reflex HPV testing is not recommended for the triage of glandular cytologic abnormalities for fear that a negative result will dissuade appropriate evaluation. However, HPV testing at time of evaluation (if not already obtained) helps distinguish cervical from endometrial disease (Castle, 2010; de Oliveira, 2006).

If initial evaluation of a glandular abnormality is negative, further management and surveillance should be guided by current clinical guidelines. Diagnostic excision is indicated for AGC, favor neoplasia or AIS cytology if initial evaluation does not reveal a cancer diagnosis.

Carcinoma. Cytology results suspicious for squamous cell carcinoma or adenocarcinoma are rare and carry the highest risk of invasive cancer. If initial evaluation fails to reveal invasive cancer, a diagnostic excision procedure is indicated.

Colposcopy

This outpatient procedure examines the LAGT, primarily the cervix. The colposcope provides a bright light source and variable magnification through an optical lens system or high-resolution digital imaging. Colposcopy requires special training, both didactic and clinical, that encompasses terminology, lesion identification and grading, and biopsy techniques. It is primarily indicated for the evaluation of abnormal cervical cancer screening tests, signs or symptoms of cervical cancer, and surveillance of treated or untreated CIN. Its primary goal is to identify invasive or preinvasive lesions for biopsy and subsequent management. However, sensitivity, interobserver agreement, and reproducibility of colposcopy are limited. Sensitivity estimates range between 50 and 80 percent (American College of Obstetricians and Gynecologists, 2018b; Ferris, 2005; Jeronimo, 2007). This highlights the need for further evaluation or surveillance testing when initial colposcopy fails to reveal high-grade neoplasia.

Prior to colposcopic examination, a woman's medical history is reviewed, and indications for colposcopy are confirmed (Table 29-5). Urine pregnancy testing is performed if clinically indicated. Colposcopic examination is optimally timed to avoid menses but is not delayed if there is a visible cervical lesion or abnormal bleeding, or if the patient is unlikely to return. In cases of severe cervicitis or other pelvic infection, treatment may be indicated before performing biopsies or endocervical curettage. However, abnormal cervical discharge without an identified pathogen may be a cancer indicator. A Pap test performed at the time of colposcopy has questionable value, may obscure colposcopic findings, and should be performed on an individualized basis.

TABLE 29-5. Clinical Considerations Directing Colposcopy

Clinical objectives
Provide a magnified view of cervix, vagina
Identify cervical squamocolumnar junction
Detect lesions suspicious for neoplasia
Direct lesion biopsy
Clinical indications
Abnormal or recurrent inadequate cervical cancer screening result
Grossly visible cervical lesion
Unexplained lower genital tract bleeding
Unexplained vaginal discharge
Contraindications: none
Relative contraindications
Upper or lower reproductive tract infection
Uncontrolled, severe hypertension
Uncooperative or overly anxious patient

Examination

A bimanual examination precedes colposcopy to detect cervical enlargement or fixation suggesting malignancy, evidence of intrauterine pregnancy, or pelvic tenderness suggesting genital tract infection. Vaginal speculum selection and placement should provide optimal inspection of the cervix and upper vagina. Solutions used during colposcopy are normal saline, 3- to 5-percent acetic acid, and Lugol iodine. Because high-grade lesions are fragile, these solutions are applied by gently dabbing with a saturated swab or sponge or by spray-bottle misting. To begin, normal saline helps remove discharge and cervical mucus and allows initial assessment of vascular patterns and surface contours. A green (red-free) light filter adds contrast to aid vascular pattern visualization (Fig. 29-9).

Acetic acid 3- to 5-percent solution is mucolytic and exerts its whitening effects, termed *acetowhitening*, presumably by reversibly denaturing cellular proteins. This causes neoplastic areas to appear denser compared with the normal surrounding epithelium, and lesions assume varying hues of transient whiteness. Several minutes may be needed for this effect to fully develop.

Lugol iodine solution stains mature, glycogen-rich squamous epithelium a dark purple-brown color in reproductive-aged women with normal serum estrogen levels. Due to incomplete maturation, dysplastic epithelium has a lower glycogen content,

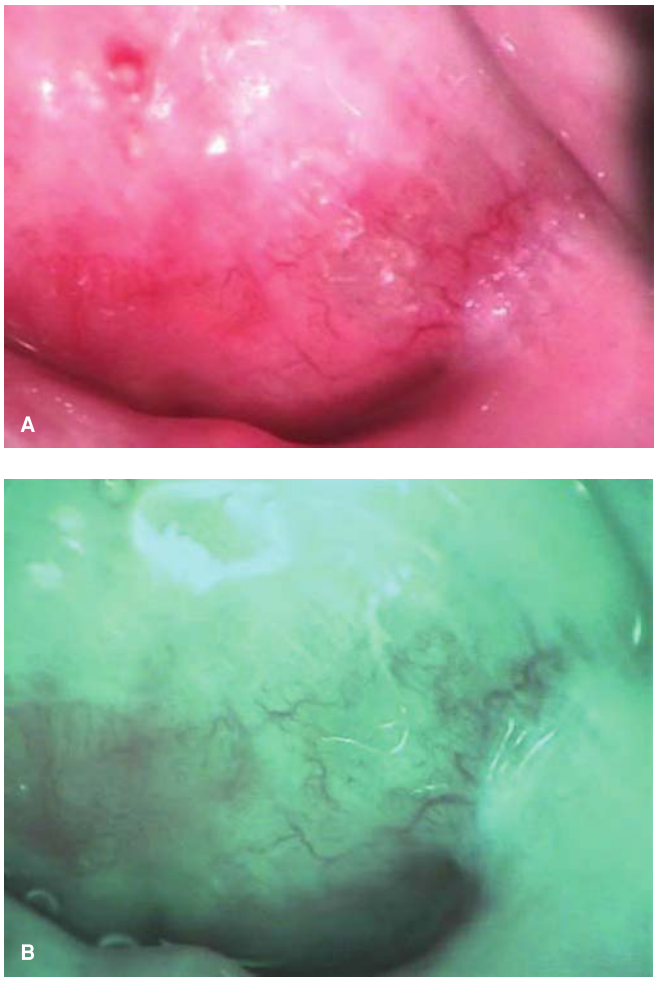

FIGURE 29-9 Evaluation of surface vessels. **A.** Benign surface vessels viewed through a colposcope using usual white light source. **B.** Use of a blue-green (red-free) light filter provides higher contrast and definition of vascular patterns.

fails to fully stain, and appears yellow (Fig. 29-10). Lugol iodine application is particularly useful when abnormal tissue is not identified using acetic acid. It is also used to define the limits of the active TZ, as cells of immature squamous metaplasia are glycogen-poor and do not stain as strongly as mature squamous epithelium. Lugol solution should not be used in patients allergic to iodine, radiographic contrast, or shellfish.

Key components of colposcopic examination include a general assessment and specific findings, described subsequently. Careful documentation of these aids neoplasia diagnosis, management, and communication between providers. Minimal and comprehensive criteria for documentation have been established by the ASCCP (Table 29-6) (Khan, 2017). Standardized colposcopic terminology used in the United States differs somewhat from that used internationally (Bornstein, 2012; Khan, 2017).

First, general assessment determines if the entire cervix and the SCJ are fully visualized. Nearly all cervical neoplasia lies within the TZ and adjacent to the SCJ. Within a dysplastic lesion, the most severe disease tends to be at its proximal (cephalad or upper) limit. Thus, complete colposcopic visualization of the cervix, SCJ, and upper limits of all lesions is essential to exclude invasive cancer and determine disease severity. When the SCJ or lesions extend into the endocervical canal, an endocervical speculum can aid in their complete visualization (Fig. 29-11).

Lesion Grading

With colposcopy, normal squamous epithelium of the cervix appears featureless, pale-pink, and smooth. Blood vessels lie below this layer and therefore are not visible or are seen as a fine capillary network. The mucin-secreting columnar epithelium appears red due to its thinness and close proximity of underlying blood vessels. Its villous appearance derives from epithelial peaks and crypts (see Fig. 29-3). Against this normal

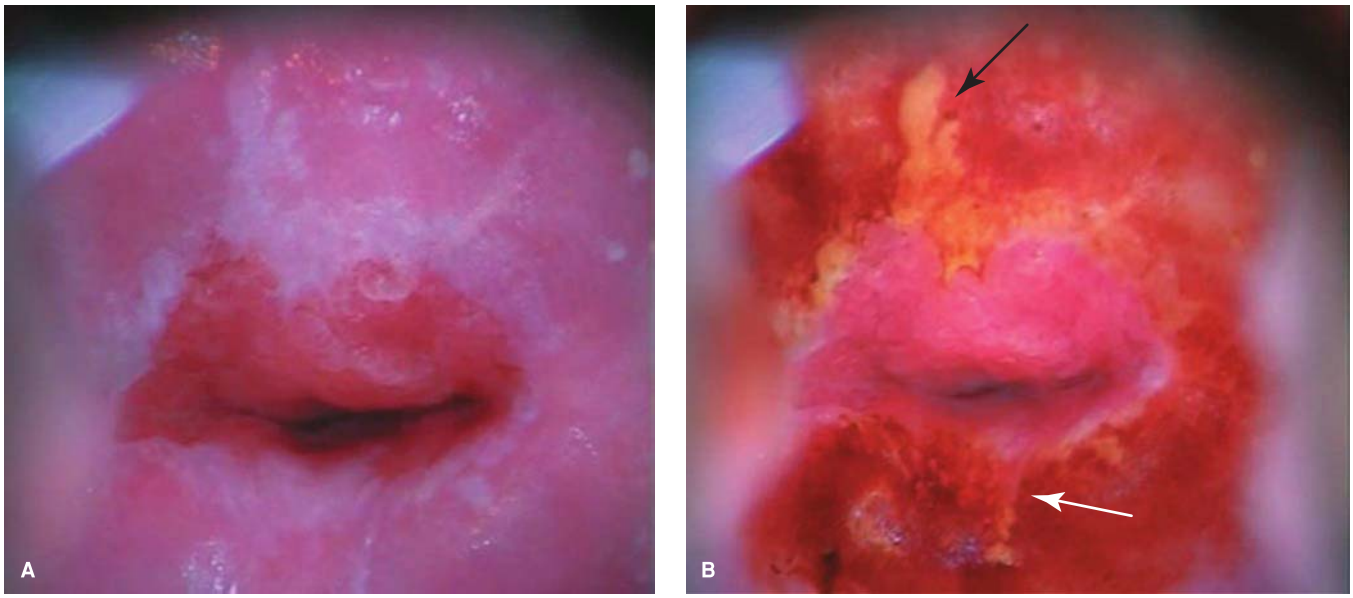

FIGURE 29-10 Solutions used for colposcopy. **A.** Cervix after application of acetic acid. Several areas of acetowhite change adjacent to the squamocolumnar junction (SCJ) are apparent. **B.** Same cervix after application of Lugol iodine solution. A nonstaining lesion at the 10 to 11 o'clock position is seen (*black arrow*), whereas an acetowhite area along the posterior SCJ (*white arrow*) shows partial iodine uptake.

TABLE 29-6. Documentation of the Colposcopic Examination

Minimum Criteria	
SCJ fully visualized	yes/no
Acetowhitening	yes/no
Lesion(s) present (acetowhite or other)	yes/no
Colposcopic impression	normal/benign; low grade; high grade; cancer
Comprehensive Criteria	
Cervix fully visualized	yes/no
SCJ fully visualized	yes/no
Acetowhitening	yes/no
Lesion(s) present (acetowhite or other)	yes/no
Lesion(s) fully visualized	yes/no
Location of lesions(s)	clock position, at SCJ?, satellite lesions
Size of lesion(s)	no. of quadrants, percentage of TZ area
Vascular changes	abnormal patterns (mosaic or punctuation), atypical vessels
Other features of lesion(s)	color, contour, borders, Lugol uptake
Colposcopic impression	normal/benign; low grade; high grade; cancer

SCJ = squamocolumnar junction; TZ = transformation zone.

colposcopic landscape, colposcopists discern abnormal tissue and biopsy the sites likely to represent the most severe neoplasia. A lesion's acetowhiteness, margins (borders), vascular patterns, size, and location relative to the SCJ help indicate the most abnormal epithelium (Table 29-7) (Khan, 2017).

After acetic acid application, the quality of whiteness obtained, the rapidity and duration of acetowhitening, and

FIGURE 29-11 An endocervical speculum can aid viewing the endocervical canal.

sharpness of lesion borders are observed over several minutes. High-grade lesions demonstrate a more persistent, duller shade of white, whereas low-grade lesions are translucent or bright white, appear slowly, and fade quickly. Generally, low-grade lesions have feathery or irregular "geographic" margins, whereas high-grade lesions have straighter, sharper outlines (Figs. 29-12 and 29-13). Other lesion features that suggest high-grade dysplasia are: internal borders (inner-border sign), an opaque, rounded protuberance (ridge sign), and cuffed crypt openings. The last are round columnar crypts ringed with thick acetowhite epithelium. Satellite lesions, which are not adjacent to the SCJ on the ectocervix, tend to be low-grade. Larger, complex lesions at the SCJ tend to be higher grade.

Abnormal vascular patterns include punctation, mosaicism, and atypical vessels. Punctate and mosaic patterns are graded based on vessel caliber, intercapillary distance, and the overall uniformity of these. Fine punctation and mosaicism, with

TABLE 29-7. Colposcopic Lesion Grading

Colposcopic Feature	Low-Grade	High-Grade	Cancer

Vascular patterns	Fine patterns	Coarse patterns	Atypical vessels
Iodine staining	Positive/Partial	Negative	Negative

FIGURE 29-12 Low-grade squamous intraepithelial lesion (LSIL). Seen after 5-percent acetic acid application, LSIL is often multifocal and bright white with irregular borders.

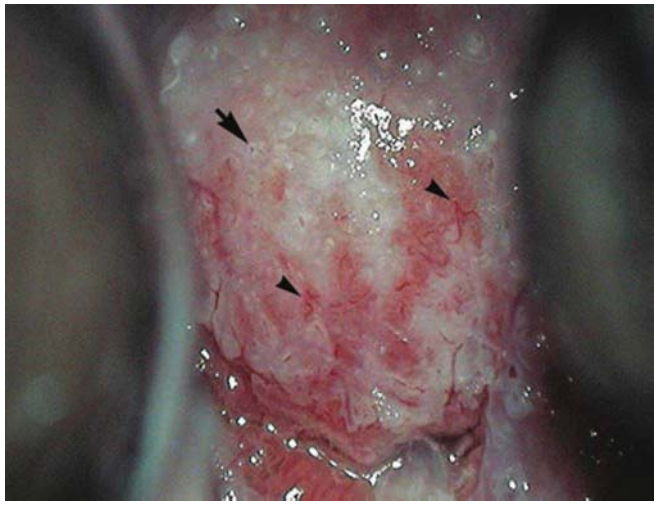

FIGURE 29-14 Colposcopy shows a large high-grade lesion with cuffed crypt openings (*arrow*) and atypical vessels (*arrowheads*) that are worrisome for invasive cancer.

narrow vessels and small, uniform intercapillary distances, typify low-grade lesions. A coarse pattern results from wide and variable vessel diameters and spacing and indicates high-grade abnormalities. Atypical vessels are irregular in caliber, shape, path, and arrangement and suggest invasive cancer (Fig. 29-14).

Importantly, malignancy often is not acetowhite due to its vascularity. Invasive cancer, especially adenocarcinoma, can create a false SCJ, and circumferential cancer mimics the redness of columnar epithelium. Thus, colposcopists should look beyond acetowhite areas to help identify invasive cancer. Moreover, areas of abnormal topography, including ulceration, should be biopsied.

Biopsy

Ectocervical Biopsy

All acetowhite lesions and other abnormalities are biopsied using cervical biopsy forceps under direct colposcopic visualization (Fig. 29-15). Generally, this does not require an anesthetic. For hemostasis, pressure with or without a swab may suffice. Thickened Monsel solution (ferric subsulfate) or a silver nitrate applicator also may be applied as needed. Heavy bleeding is rare and can be controlled with direct pressure. Rarely, brief vaginal packing is needed.

Traditionally, biopsies targeted only the most severe-appearing lesion(s). However, colposcopic impression is often inaccurate and can underestimate the level of disease. Thus, limiting sampling to a single biopsy can miss a significant amount of CIN (Gage, 2006). Therefore, recommendations encourage biopsy of all acetowhite areas; two to four biopsies of abnormalities are recommended for optimal sensitivity (American College of Obstetricians and Gynecologists, 2018b; Wentzensen, 2017).

New evidence-based standards provide further biopsy guidance based on an individual's risk of high-grade CIN. Risk estimates are derived from referral screening test results and colposcopic impression (Wentzensen, 2017). For those at

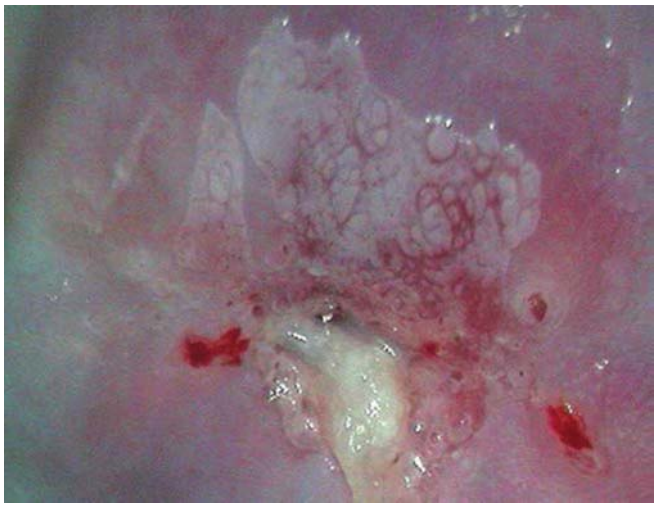

FIGURE 29-13 High-grade squamous intraepithelial lesion (HSIL). After 5-percent acetic acid application, HSIL demonstrates an off-white dull color and coarse vascular pattern.

FIGURE 29-15 Tools used for cervical evaluation and biopsy. From top to bottom: endocervical curette, endocervical speculum, and cervical biopsy forceps.

lowest risk of high-grade neoplasia (cytology result less than HSIL, no positive HPV 16/18 results, normal colposcopy without acetowhitening), untargeted (random) biopsies are not recommended. At the other extreme, patients at highest risk are those with cytology reflecting HSIL or worse, positive HPV 16 or 18 testing results, and a colposcopic impression suggesting HSIL. In such patients who are aged ≥25 years and not pregnant, an immediate excision procedure or colposcopy with directed biopsies is acceptable.

Endocervical Sampling

For nonpregnant patients, endocervical sampling by curettage or brushing evaluates the endocervical canal epithelium lying beyond the colposcopist's view. Endocervical sampling is currently recommended during colposcopy for the following situations (American College of Obstetricians and Gynecologists, 2018b; Massad, 2013):

- The SCJ is not fully visualized.
- The SCJ is fully visualized, but no lesion is identified.
- Initial evaluation of ASC-H, HSIL, AGC, or AIS cytology test results.

These indications may change as evidence-based guidelines are updated.

Endocervical curettage is performed by introducing an endocervical curette 1 to 2 cm into the cervical canal (see Fig. 29-15). The length and circumference of the canal is firmly curetted, carefully avoiding sampling of the ectocervix or the lower uterine segment. Endocervical scrapings admixed with cervical mucus are then removed using a ring forceps or a cytobrush and included with the curettage specimen. Alternatively, vigorous brushing with a cytobrush may be used for endocervical sampling. Endocervical brushing is more sensitive than curettage, but grading of any dysplasia present is more difficult. It is also acceptable to perform curettage followed by a brushing to enhance sensitivity and grading of any abnormality present. Endocervical sampling is often the most uncomfortable part of a colposcopic evaluation, and cramping is common. Tissue from endocervical sampling is always sent separately from ectocervical biopsies for histologic evaluation.

Pregnancy

Pregnancy does not alter the natural history of cervical disease. Pregnancy is an opportunity to screen patients aged ≥21 years as indicated. Abnormal cytology is managed according to guidelines for the general population with only a few variations. When colposcopy is indicated, its primary goal during pregnancy is to exclude invasive cancer. Colposcopy and biopsy are safe and accurate during pregnancy (Economos, 1993). The number of biopsies is limited to areas of greatest concern. Endocervical and endometrial sampling are never performed during pregnancy to avoid amnionic membrane rupture, infection, or other harm to the pregnancy. CIN is reevaluated postpartum since lesion grade frequently changes after delivery and puerperal remodeling (Yost, 1999). Although cervical conization is infrequently performed during pregnancy, indications for this are discussed in Chapter 30 (p. 672).

CERVICAL INTRAEPITHELIAL NEOPLASIA MANAGEMENT

CIN management may be surveillance or treatment. Evidence-based guidelines for the management of women with biopsy-confirmed (histologic) CIN have been developed by the ASCCP and continue to evolve as new data is available (Massad, 2013). Current guidelines are found at www.asccp.org. During CIN management, the detection and prevention of invasive cervical cancer, a relatively rare outcome, must be balanced against the potential harms of excessive testing and overtreatment. Potential harms include procedure-related morbidity, psychologic stress, and possible adverse reproductive outcomes.

Special populations considered include younger and pregnant women. Despite differences in screening recommendations, immunocompromised women are no longer considered a special population for CIN management and typically are managed in accordance with general guidelines (Massad, 2013; Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents, 2019). CIN severity, colposcopic findings, age, and reproductive plans play key roles in cervical disease management. Guidelines are complex and applied on an individualized basis. They cannot address all patient scenarios and cannot prevent all cases of cervical cancer.

CIN 1

Histologic LSIL (HPV changes or CIN 1) exhibits high rates of spontaneous regression. The LSIL diagnosis is poorly reproducible by cytology or histology and is thus unreliable. Therefore, patients should not be told they have HPV infection based upon LSIL cytology or biopsy alone. For these reasons, HPV change found by biopsy is not treated, and CIN 1 is no longer treated immediately. When diagnosed after a "lesser" cytologic abnormality such ASC-US, LSIL, or an NILM, HPV-positive screening, it can be observed indefinitely. Treatment is acceptable only if CIN 1 persists for more than 2 years. This is regardless of colposcopic examination adequacy or presence of CIN 1 in an endocervical sampling. Treatment of CIN 1 in younger women or those concerned about the possible effects of treatment on future pregnancy is discouraged. Current guidelines for surveillance without treatment and criteria that return a woman to routine screening should be followed and may involve periodic cytology or co-testing.

If deemed appropriate, persistent CIN 1 can be treated by ablation. Criteria require that the SCJ and all lesions are fully seen during colposcopy and that the endocervical sampling lacks HSIL (CIN 2/3) or ungraded CIN. If these criteria are not met and treatment is indicated, excision is recommended and ablation is unacceptable.

CIN 1 diagnosed after an ASC-H or HSIL Pap test result carries a higher risk of undiagnosed high-grade CIN. Depending on patient age and colposcopic findings, either a diagnostic excision or surveillance with colposcopy, cytology, HPV testing, or a combination of these at prescribed intervals will be recommended by current guidelines. Persistent, unexplained HSIL or AGC cytology generally warrants an excision procedure, if only CIN 1 is found with colposcopic biopsy.

HSIL: CIN 2 and CIN 3

Generally, treatment is recommended for CIN 2 or CIN 3 because of the significant malignant potential of HSIL and the efficacy of treatment to eradicate precancers. Treatment modalities include either ablation or excision of the entire TZ. Excision is greatly favored over ablation in the United States. Treatment is tailored to the individual patient, lesion, and anatomic characteristics.

An unequivocal histologic diagnosis of CIN 3 is always treated and not observed in nonpregnant patients regardless of age or reproductive history. With a CIN 3 biopsy, if HSIL or ungraded CIN is found in the endocervical sampling or if colposcopy did not fully visualize the SCJ and the upper limits of all lesions, a diagnostic excision is indicated to exclude occult invasive cervical cancer. Recurrent or persist HSIL after treatment is managed with repeat excision, not ablation. Hysterectomy as primary therapy is unacceptable. Hysterectomy may be indicated if repeat excision is needed but not anatomically feasible or if high-grade CIN recurs or persists and invasive cancer has been thoroughly excluded.

For young women, particularly of low parity, with CIN 2 or HSIL (CIN 2/3, not otherwise specified) surveillance or treatment is acceptable, if the SCJ and all lesions are fully seen during colposcopy. In this context, "young women" refers to individuals for whom the possible risk to future pregnancies from treatment outweighs the risk of progression to malignancy, although both are difficult to quantify. No upper age limit is specified for surveillance. Surveillance of specified CIN 2 is preferred in younger women, because this histologic diagnosis is less reliable and spontaneous regression of lesions over time is common. Even in younger women or those concerned with future reproduction, treatment is indicated if colposcopy does not fully visualize the SCJ and lesions present, biopsy shows CIN 3, or if CIN 2 or CIN 2/3 is persistent. Current guidelines for surveillance testing, intervals for reassessment, and acceptable upper time limits for persistence should be consulted.

Adenocarcinoma in Situ

Cervical AIS, although uncommon, is rising in incidence (Herzog, 2007). Exclusion of coexistent invasive cancer and removal of all affected tissue are primary goals. High-grade squamous lesions often accompany glandular neoplasia. However, management differs somewhat from that of HSIL, because cervical AIS and adenocarcinoma are not as easily identified colposcopically as squamous lesions. Moreover, AIS can be multifocal, lie deep within endocervical crypts, and extend high into the endocervical canal (Massad, 2013). Thus, diagnostic excision is recommended to exclude invasive cancer with maximum certainty. The choice of excision modality should favor obtaining an intact specimen with the most interpretable margins. Thus, cold-knife conization is favored over loop electrosurgical excision procedure (LEEP). If the excised specimen shows no invasive cancer, hysterectomy is recommended in women who have completed childbearing.

Women with AIS who strongly desire fertility preservation may be managed conservatively after an excision procedure. Individuals are counseled regarding the significant ongoing risk even with negative excision margins. The risk of residual AIS is reported to be as high as 80 percent in patients with positive margins (Krivak, 2001). Accordingly, if timely hysterectomy is not planned, repeat excision is advisable for managing positive margins. Close, long-term surveillance is recommended until hysterectomy is performed (Massad, 2013).

Postcolposcopy Surveillance without Treatment

When colposcopy following abnormal screening tests fails to diagnose a high-grade precancer or there is spontaneous regression of high-grade CIN in younger women, further surveillance is indicated. Guidelines recognize the significant false-negative rate of colposcopy and the increased risk of developing CIN in the future. Surveillance involves repeat cytology, HPV testing, or colposcopy alone or in combination at specific intervals depending on the original abnormal cytology result, patient age, and current guidelines. Exceptions are AGC, favor neoplasia and AIS Pap test results. These are always followed by excision unless invasive cancer is diagnosed during initial colposcopic examination and biopsy.

CERVICAL INTRAEPITHELIAL NEOPLASIA TREATMENT

Current treatment of CIN is limited to ablation or excision procedures targeting the entire TZ. Thus, individual cervical lesions are not treated. Any treatment ideally should reach a depth of 5 to 7 mm from the surface to treat CIN adequately. Excessive depth is avoided to minimize potential complications. Treatments with topical agents or therapeutic vaccines remain investigational. Selection of treatment modality is individualized based on several factors including patient age, parity, size and severity of lesions, cervix contour and anatomy, prior CIN treatment, and coexisting medical conditions. Treatment selection also depends on provider experience and available equipment. Surgical treatments have an approximate 90-percent success rate (Martin-Hirsch, 2013). A review of clinical considerations is provided by Khan and Smith-McCune (2014).

Ablation

This involves physical destruction of tissue and is generally effective for noninvasive ectocervical disease. Before ablation, glandular neoplasia or invasive cancer are excluded with the greatest possible certainty. To this end, cytology, histology, and colposcopic impression should be concordant. Further, the entire SCJ and proximal (upper) limits of all lesions should be visualized during colposcopy and endocervical sampling should be negative for high-grade or ungraded CIN. Ablation should not be used after previous therapy, after glandular cytologic abnormalities, or for AIS.

The most commonly used ablative treatment modalities are cryosurgery and carbon dioxide (CO_2) laser. Both techniques are illustrated in Section 43-28 (p. 1004). Before the introduction of LEEP, when cold-knife conization was the only excisional option, these ablative techniques were commonly used.

However, the relative decreased morbidity and ease of performing LEEP compared with cold-knife conization has led to a decline in ablative procedures. The trend toward surveillance of CIN 1 and some CIN 2 and HSIL (CIN 2/3 lesions) in young women also is contributory.

Cryosurgery is an ablative method that delivers nitrous oxide to a metal probe that freezes tissue on contact. Cryonecrosis is achieved by crystallizing intracellular water. This treatment is most appropriate for entirely ectocervical lesions and SCJ, a smooth cervical surface without deep crevices, circumferential cervical length adequate to avoid thermal damage to the vaginal walls, and CIN limited to two quadrants of the cervix. Cryosurgery is not favored for the treatment of CIN 3 due to higher rates of disease persistence following treatment and lack of a histologic specimen to exclude undiagnosed invasive cancer (Martin-Hirsch, 2013). Moreover, cryosurgery and other ablative techniques are not favored for women with HIV infection and CIN due to higher failure rates (Spitzer, 1999).

CO_2 laser is another ablative option and is delivered using colposcopic guidance. Cervical tissue is vaporized to a depth of 5 to 7 mm. Laser ablation is appropriate for CIN if lesions and TZ are fully seen during colposcopy. It is well suited for large, irregularly shaped CIN lesions of all grades and for condylomatous and preinvasive lesions at other LAGT sites. If a cervical lesion extends onto the vagina, laser ablation may allow customized removal of the entire lesion. Laser ablation can be augmented by excision of central tissue for cases in which an ectocervical lesion extends into the endocervical canal or when the SCJ is not fully visualized (American College of Obstetricians and Gynecologists, 2018b).

Excision

Excision procedures are favored when the risk of invasive cancer is significant. Examples are antecedent high-grade cytologic abnormalities including ASC-H, HSIL, AGC, and AIS; cases in which the SCJ or lesions are not fully visualized during colposcopy; CIN 3 or AIS histology; or endocervical sampling that indicates ungraded or high-grade CIN or glandular neoplasia. An advantage of excision compared with ablation is provision of a histologic specimen to confirm the absence of invasive cancer and to evaluate involvement of the excised margins. With glandular cytologic abnormalities or AIS biopsy, an excision technique that provides an intact specimen with the most interpretable margins should be chosen, usually cold-knife conization (Massad, 2013). Excision is also indicated for persistence or recurrence of high-grade CIN after treatment (Paraskevaidis, 1991). *Diagnostic excision* refers to situations in which invasive cancer has not been excluded by standard colposcopic criteria. A *therapeutic excision* is performed for treatment of CIN that is fully diagnosed and criteria to exclude invasive cancer have previously been met by colposcopy and biopsy.

Excisional modalities include LEEP, also known as LLETZ (large loop excision of the transformation zone); cold-knife conization (CKC); and laser conization. These are illustrated in Section 43-27 of the atlas (p. 999). The superiority of one excision technique compared with others has not been demonstrated conclusively for any particular indication. Excisional procedures have operative and long-term risks that include bleeding, cervical stenosis, and adverse pregnancy outcomes. CKC is associated with cervical incompetence and preterm birth. The relationship between preterm birth and LEEP remains uncertain. Although some studies show LEEP to be an independent risk factor for preterm birth and premature rupture of membranes, others do not. An important confounder is the greater risk of preterm birth in women with cervical neoplasia, even if they have not undergone treatment, compared with the general population. This indicates that CIN and preterm birth have overlapping risk factors, making the contribution of treatment to this already increased risk difficult to ascertain and controversial (Gatta, 2017).

TABLE 29-8. Loop Electrosurgical Excision Procedure: Clinical Characteristics

Advantages
Favorable safety profile
Ease of procedure
Outpatient procedure using local anesthesia
Low-cost equipment
Tissue specimen for histopathology evaluation
Disadvantages
Thermal damage may obscure specimen margin status
Special training required
Risk of postprocedure bleeding
Theoretical risk of vapor plume inhalation

LEEP involves a thin wire loop through which an electrical current passes. This can simultaneously cut and coagulate tissue, ideally during direct colposcopic visualization. As advantages, LEEP can be performed with local anesthesia, often in an office setting, and with low complication rates. Additionally, the size and shape of tissue excision can be tailored by varying loop size and the order in which loops are used. This helps conserve cervical stroma volume (Table 29-8).

Cold-knife conization uses sharp excision to remove the cervical TZ and precancerous tissue. It is performed under general or regional anesthesia. CKC may be preferred to LEEP for patients at highest risk for invasive cancer. Examples are those with cytology suggesting invasive cancer, patients older than 45 with CIN 3 or CIS, large high-grade lesions, and glandular cytologic abnormalities or AIS (Table 29-9).

CO_2 laser conization is only rarely used currently. It allows precise tailoring of the cone shape to minimize excision volume and yields less blood loss than CKC. Disadvantages are its high equipment expense, some thermal compromise of specimen margins, and special training requirements. This procedure can be performed under local, regional, or general anesthesia.

Surveillance after Treatment or Regression

Post-treatment surveillance with cytology, HPV testing, and/or colposcopy is required to confirm treatment success (American College of Obstetricians and Gynecologists, 2018b; Massad, 2013). After excision, surveillance will be influenced by margin status. After treatment for high-grade cervical dysplasia or invasive cancer, screening continues for at least 20 years, even if

TABLE 29-9. Cold-Knife Conization Clinical Characteristics

Advantages
Anesthetized patient
Tissue specimen without margin compromise
Enhanced patient support if hemorrhage is encountered
Variety of instruments to individualize conization
Disadvantages
Potential for hemorrhage
Lengthier procedure
Postoperative discomfort
General or regional anesthesia required
Operating room setting
High cost
Larger volume of cervical stroma removed
Increased risk of adverse reproductive outcomes

screening extends beyond age 65. This stems from a persistently higher risk of cervical neoplasia. Current guidelines should be consulted to guide long-term screening of patients based on their particular histories.

If an excision margin or endocervical curettage performed immediately after an excision is positive for HSIL (CIN 2 or CIN 3), repeat excision may be indicated. Repeat excision is indicated for special circumstances such as AIS or microinvasive carcinoma at the excision margins.

Hysterectomy

Hysterectomy is unacceptable as primary therapy for CIN (American College of Obstetricians and Gynecologists, 2018b; Massad, 2013). However, it may be considered when treating recurrent high-grade cervical disease if childbearing has been completed or if a repeat cervical excision is strongly indicated but not technically feasible. Although hysterectomy provides the lowest CIN recurrence rate, invasive cancer must always be excluded beforehand. The chosen route of hysterectomy is directed by other clinical factors. Hysterectomy is the preferred treatment of AIS, if future fertility is not desired and excision has excluded invasive cancer.

Even with negative cervical margins, hysterectomy performed for CIN 2 or worse is not completely protective. Patients, particularly those who are immunosuppressed, are at risk for recurrent disease and require postoperative periodic cytologic screening of the vaginal cuff (p. 631). This should be accompanied by palpation and visual inspection of the cuff for nodularity or lesions.

VAGINAL INTRAEPITHELIAL NEOPLASIA

Pathophysiology

Primary vaginal carcinoma is rare and makes up <5 percent of all gynecologic malignancies (Siegel, 2019). In the United States, 5350 new cases of vaginal cancer will be diagnosed in 2019 (American Cancer Society, 2019b). Nearly 50 percent of cases are diagnosed in women aged ≥70 years (Kosary, 2007). Approximately 90 percent of vaginal cancers are squamous cell carcinomas. These appear to develop slowly from precancerous epithelial changes, called *vaginal intraepithelial neoplasia (VaIN)*, in a fashion similar to cervical cancer from CIN. Due to its rarity, VaIN and its natural history, treatment efficacy, and risk of recurrence or progression are not well understood.

VaIN demonstrates histopathology similar to CIN. It is rarely found as a primary lesion and most often develops as an extension of CIN, mainly in the upper third of the vagina (Diakomanolis, 2002; Hoffman, 1992a). Unlike the cervix, the vagina lacks a TZ that is susceptible to HPV-induced neoplasia. However, HPV may gain entry from vaginal mucosal abrasions and reparative metaplastic squamous cell activity (Woodruff, 1981). In one review, HPV DNA was found in up to 98 percent of VaIN lesions and in three quarters of vaginal cancers. HPV 16 is the most common type (Alemany, 2014). Thus, HPV vaccination against oncogenic HPV types 16 and 18 has the potential to also prevent vaginal cancers (Smith, 2009).

Cervical and vulvar neoplasia raise the risk for VaIN and vaginal squamous cell cancer, especially in women aged >60 years (Strander, 2014). Moreover, one retrospective study suggests that hysterectomy for CIN is not definitive therapy for high-grade neoplasia, because the subsequent high-grade VaIN recurrence rate exceeded 7 percent (Schockaert, 2008).

Diagnosis

Generally, VaIN is asymptomatic and abnormal cytology results are often the first indication. If present, symptoms may include spotting, discharge, and odor. Subsequent examination of the vagina with a colposcope, termed *vaginoscopy*, frequently identifies a lesion for biopsy. Prior to visual evaluation, careful palpation of the vagina is advised, particularly if the patient has undergone hysterectomy for high-grade cervical neoplasia. In such cases, invasive cancer may present as a nodular lesion buried within the vaginal cuff before it becomes visible.

During vaginoscopy, inspecting the vagina using a colposcope can be challenging because of a large surface area, rugation, and surfaces that lie parallel to the colposcope's visual axis. Particular attention is paid to the upper third of the vagina due to the common etiology of VaIN as an extension of CIN. By applying 3- to 5-percent acetic acid to the vaginal mucosa, acetowhite changes consistent with HPV infection or neoplasia can be identified (Fig. 29-16). Vascular patterns are less common in VaIN lesions than with CIN, but coarse punctation and even atypical vessels may be seen in high-grade and invasive lesions. High-grade VaIN lesions tend to demonstrate flat, dense acetowhitening with sharply demarcated borders. Half-strength Lugol solution applied to the vagina further delineates abnormal areas. Areas with the least staining and straightest lesion margins are most suspicious.

Local anesthesia is usually not necessary for biopsy of the vagina's upper third but may be needed for more distal sites. Biopsy may be obtained by means of a cervical biopsy forceps (see Fig. 29-15), and an Emmett hook can be used to elevate and stabilize vaginal tissue if needed. The vaginal tissue is grasped and lifted to limit the biopsy depth. Menopausal

FIGURE 29-16 Vaginoscopy showing multifocal acetowhite human papillomavirus (HPV) lesions after application of 5-percent acetic acid.

women may have significant thinning of the vaginal mucosa. Thus, biopsies, possibly with a smaller biopsy forceps, are shallow to avoid vaginal wall perforation. Hemostasis is achieved using silver nitrate applicators or Monsel paste. Vaginal lesion size, location, and specific biopsy sites are carefully documented for future management and surveillance.

Management

Similar to high-grade CIN, high-grade VaIN is believed to be a precancerous lesion and generally warrants eradication (Punnonen, 1989; Rome, 2000). Because vaginal neoplasia is uncommon, most management strategies are derived from small, retrospective, and statistically underpowered studies. Management of VaIN is influenced by histologic diagnosis; neoplasia grade; and lesion size, number, and location. Options are observation, excision, ablation, topical antineoplastics, or, rarely, radiation therapy. Each treatment method has advantages and disadvantages and none has proven superior efficacy. Thus, comprehensive patient counseling and shared decision-making are essential.

Low-Grade VaIN

Lesions interpreted as vaginal LSIL often represent atrophy or transient HPV infection. Spontaneous regression is common. Thus, observation is preferable in most cases, and aggressive treatment is avoided. For example, in one long-term study of 132 patients with biopsy-proven VaIN, an observational approach resulted in VaIN 1 regression in seven of eight patients (88 percent) (Rome, 2000). No VaIN 1 lesion progressed to high-grade VaIN or invasive cancer. Without evidence-based guidelines, surveillance similar to that for low-grade CIN seems reasonable. Thus, cytology with or without vaginoscopy is completed every 6 to 12 months until abnormalities resolve or progress to HSIL.

High-Grade VaIN

Hodeib and colleagues (2016) reported no clear risk factors and no specific primary treatment as significantly more predictive or effective in preventing recurrence after following the clinical course of 42 patients with biopsy-proven VaIN 2/3. Observation of VaIN 2 may be considered in selected patients, although the safety of this approach is not established. The treatment choice for patients with high-grade VaIN is influenced by the location and number of lesions, the patient's sexual activity status, vaginal length, prior radiation therapy, previous treatment modalities in patients with recurrent VaIN, and clinician experience. Potential adverse treatment effects such as pain, difficulties with sexual intercourse, and scarring are always considered.

Wide local excision of a high-grade unifocal lesion or partial vaginectomy for multifocal lesions may be selected. Hoffman (1992a) found that 9 of 32 patients (28 percent) with prior hysterectomy and VaIN 3 had occult invasive cancer in the vaginal cuff. Therefore, surgical excision is considered for high-grade lesions involving the vaginal cuff, particularly if any thickening or nodularity of the vaginal apex suggests occult invasive disease. Excisional procedures have the advantage of providing a surgical specimen for which resected-margin status can be determined and the presence of invasive vaginal cancer excluded. Partial vaginectomy is surgically challenging but has the highest cure rate and fewest recurrences for high-grade disease (Dodge, 2001).

Wide local excision carries less morbidity than vaginectomy, but both procedures may be complicated by bladder or rectal injury and hemorrhage. In addition, subsequent vaginal scarring and stenosis may compromise vaginal intercourse or cause dyspareunia. Sharp dissection is favored for wide local excision and partial vaginectomy. Laser causes significant thermal damage to the tissue specimen and generally is not recommended for excision of vaginal mucosa. Loop excision has poor depth control, carries a substantial risk of thermal damage to underlying pelvic structure, and is not recommended for vaginal surgery.

CO_2 laser ablation is an option for lesions not concerning for invasive disease. It is well suited to eradicate multifocal lesions and causes less scarring and blood loss than tissue excision. Rarely, hemorrhage and thermal damage to the bladder and bowel can occur. In one small case study of 21 patients undergoing CO_2 laser ablation for high-grade VaIN, 14 percent had persistent disease requiring retreatment. One patient progressed to invasive carcinoma, which underscores the importance of long-term surveillance (Perrotta, 2013). A broader explanation of laser ablation techniques is found in Section 43-28 of the atlas (p. 1005).

Topical therapy, as with ablative procedures, is suitable if invasive disease is not suspected based on findings from cytology, vaginoscopy, or histology. Persistent VaIN 2 and selected VaIN 3 lesions may be medically treated using 5-percent fluorouracil (5-FU) cream "off-label," as it is not FDA approved for this specific indication (Krebs, 1989). Although 5-FU's efficacy is unproven in large, randomized trials, Fiascone and colleagues (2017) found a 74-percent success rate and no recurrences in 47 patients with high-grade VaIN.

Treatment regimens vary widely. One dosing schedule calls for a 3-mL dose of cream placed into the vaginal vault by plastic vaginal applicator every other day during the first week of treatment and once weekly thereafter for up to 10 weeks. 5-FU cream is often associated with a robust inflammatory reaction that can include vaginal burning and vulvar irritation. To minimize leakage onto the vulva, cream is best applied intravaginally at bedtime, when a recumbent position will be maintained for hours. Additionally, an occlusive, water-resistant ointment can

be spread on the vulva for protection. Protective gloves are worn when handling 5-FU cream, and measures are taken to avoid 5-FU contact by sexual partners.

Patients selected for this treatment require thorough counseling, effective contraception as needed, and consent for off-label medication use. Close monitoring observes for excessive inflammation and ulceration, which can lead to vaginal or vulvar scarring and loss of function.

Radiation therapy has a very limited role for high-grade VaIN treatment. It carries a significant risk of serious morbidity and is reserved for select cases. In a review of 136 cases of vaginal carcinoma in situ, radiation therapy was used in 27 patients, and a 100-percent cure rate was noted. However, 63 percent developed significant complications that included vaginal stenosis, adhesions, ulceration, necrosis, and fistula formation (Benedet, 1984). Furthermore, radiation treatment compromises subsequent cytologic, colposcopic, and histologic interpretation. Disease recurrence often necessitates radical surgery.

Prognosis

In a study of 132 patients treated for high-grade VaIN, excision and CO_2 laser ablation had equal cure rates of 69 percent. Topical 5-FU cream was curative in 46 percent of cases (Rome, 2000). For treatment of recurrent high-grade VaIN, a lower disease recurrence rate was associated with CO_2 laser ablation compared with medical treatment (Bogani, 2019). Patients with any grade of vaginal neoplasia require long-term monitoring, because the persistence and recurrence rate for high-grade disease is significant. Currently, no evidence-based guidelines are available for posttreatment surveillance of VaIN. Monitoring includes collection of vaginal cytology and performance of vaginoscopy approximately 2 to 4 months after treatment is completed. Continued surveillance with periodic cytology with or without vaginoscopy at 6- to 12-month intervals for several years thereafter seems prudent. Long-term cytologic screening is needed thereafter.

VULVAR INTRAEPITHELIAL NEOPLASIA

Pathophysiology

Vulvar cancer is rare, and in 2019, it is predicted to make up approximately 6 percent of all gynecologic cancers and <0.7 percent of all cancers in U.S. women (American Cancer Society, 2019c). Of vulvar cancers, 90 percent are squamous cell and in some cases may develop slowly from VIN (Fig. 29-17) (Judson, 2006).

HPV DNA has been found in up to 80 percent of VIN lesions. (Del Pino, 2013). However, vulvar cancer is not

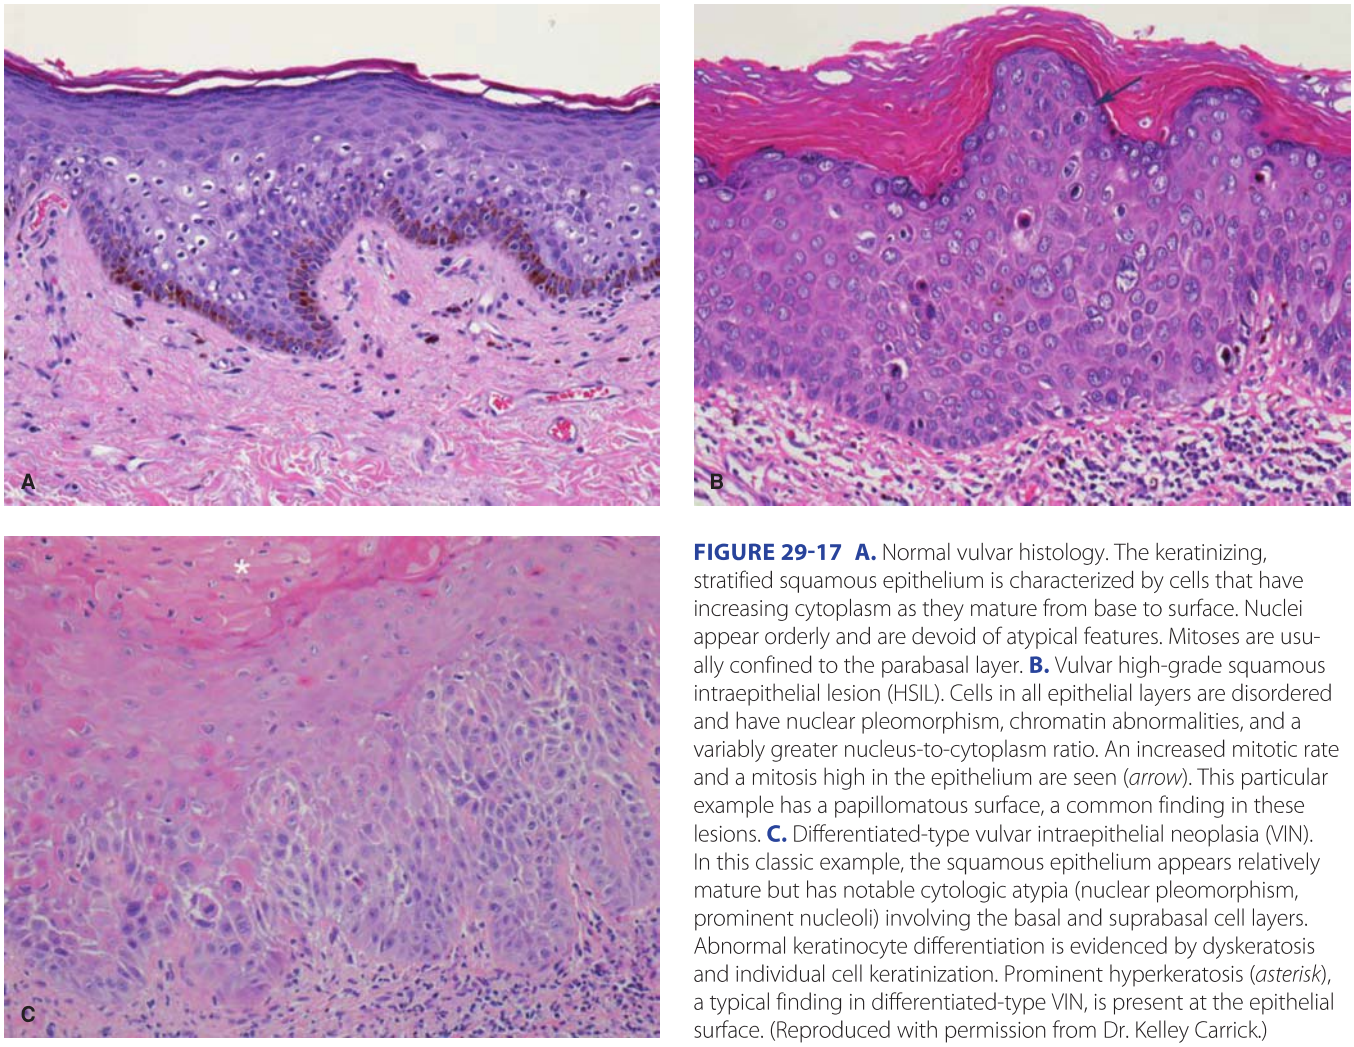

FIGURE 29-17 A. Normal vulvar histology. The keratinizing, stratified squamous epithelium is characterized by cells that have increasing cytoplasm as they mature from base to surface. Nuclei appear orderly and are devoid of atypical features. Mitoses are usually confined to the parabasal layer. **B.** Vulvar high-grade squamous intraepithelial lesion (HSIL). Cells in all epithelial layers are disordered and have nuclear pleomorphism, chromatin abnormalities, and a variably greater nucleus-to-cytoplasm ratio. An increased mitotic rate and a mitosis high in the epithelium are seen (*arrow*). This particular example has a papillomatous surface, a common finding in these lesions. **C.** Differentiated-type vulvar intraepithelial neoplasia (VIN). In this classic example, the squamous epithelium appears relatively mature but has notable cytologic atypia (nuclear pleomorphism, prominent nucleoli) involving the basal and suprabasal cell layers. Abnormal keratinocyte differentiation is evidenced by dyskeratosis and individual cell keratinization. Prominent hyperkeratosis (*asterisk*), a typical finding in differentiated-type VIN, is present at the epithelial surface. (Reproduced with permission from Dr. Kelley Carrick.)

exclusively a result of HPV infection, and rates of association range from 15 to 80 percent (Del Pino, 2013). The vulva, unlike the cervix, has no TZ, and the effect of HPV infection on the vulva's keratinized epithelium is not biologically comparable to that on the cervix or anus.

Compared with CIN, VIN less often progresses to high-grade disease and cancer. However, one study identifying trends in the incidence of vulvar carcinoma in situ found a fourfold rise from 1973 to 2000. This trend is particularly pronounced in younger women and is thought to be linked to the increased incidence of STDs, including HPV (Howe, 2001). Jones and coworkers (2005) report that the mean age of women with VIN has declined from 50 to 39 years since 1980.

Although spontaneous regression has been reported, high-grade VIN is a premalignant condition and should be treated (American College of Obstetricians and Gynecologists, 2019). In one New Zealand study, 10 of 63 patients receiving no treatment for high-grade VIN developed vulvar cancer (Jones, 2005).

Classification

Terminology for squamous VIN was adopted as a general category of intraepithelial squamous neoplasia by the International Society for the Study of Vulvar Disease (ISSVD) in 1986 (Wilkinson, 1986). Under this traditional classification, VIN grades 1, 2, and 3 were defined by abnormal cellular changes found to varying thicknesses within the squamous epithelium, similar to CIN. The term *differentiated-type VIN 3* was also introduced to include histologic cases exhibiting cells with prominent eosinophilic cytoplasm and keratin changes in the involved epithelium (Wilkinson, 1986).

In 2015, to recognize the 2012 Lower Anogenital Squamous Terminology (LAST) developed by the ASCCP and College of American Pathologists, the ISSVD further revised VIN terminology by incorporating a modified form of the World Health Organization classification of tumors on the vulva (Bornstein, 2016; Crum, 2014; Darragh, 2012). The rationale for the 2015 ISSVD terminology change was to provide consistent nomenclature of HPV-associated squamous lesions of the lower genital tract.

Current ISSVD terminology adopted by the American College of Obstetricians and Gynecologists (2019) is summarized in Table 29-10. VIN now has three categories of squamous intraepithelial lesions (SIL): vulvar low-grade SIL (vulvar LSIL, flat condyloma, or HPV effect); vulvar high-grade SIL (vulvar HSIL, VIN usual type); and differentiated VIN. Vulvar HSIL lesions are commonly associated with oncogenic HPV infection, particularly HPV 16 (Smith, 2009). In general, HPV-related high-grade VIN lesions histologically resemble high-grade CIN and tend to be multifocal (Feng, 2005; Haefner, 1995).

The entire lower genital tract is vulnerable to HPV infection. Risk factors for vulvar HSIL are similar to those for VaIN and CIN. Accordingly, vulvar HSIL is associated with HPV risk factors (p. 624) (Hoffman, 1992b; Jones, 2005). Tobacco smoking is strongly linked with vulvar HSIL, and cessation is encouraged (American College of Obstetricians and Gynecologists, 2019).

In contrast, differentiated VIN is less common and accounts for only 2 to 10 percent of all VIN cases (Hart, 2001). Such lesions tend to be unifocal and are typically found in older, nonsmoking, postmenopausal women in their sixth and seventh decade. Infection with oncogenic HPV is uncommon and probably does not play a role in the genesis of these lesions. Instead, they tend to arise in a background of inflammatory dermatosis, particularly lichen sclerosus. Approximately 60 percent of vulvar squamous cell carcinoma presents independently of HPV infection, and the unproven but likely precursor may be differentiated VIN (Bigby, 2016). One study noted that progression of differentiated VIN to vulvar squamous cell carcinoma was five times higher than for vulvar HSIL (van de Nieuwenhof, 2009). Vulvar cancers arising in a background of differentiated VIN also have higher recurrence rates (Eva, 2008). The pathologic diagnosis of differentiated VIN is difficult, and interobserver agreement is low. If clinical findings warrant, review by an experienced gynecologic pathologist may be helpful (van den Einden, 2013).

Other rare intraepithelial vulvar neoplasms include melanoma and Paget disease. These remain unclassified and may require specialty consultation.

TABLE 29-10. Vulvar Squamous Intraepithelial Lesion: Terminology and Characteristics

VIN Type	Clinical Presentation and Risk Factors
Vulvar LSIL	Formerly VIN 1 HPV effect Flat lesions with basal atypia and koilocytic changes such as condyloma Self-limited lesions, not precancerous
Vulvar HSIL	Formerly VIN usual type (VIN 2, VIN 3, vulvar CIS) Younger women Multicentric and multifocal disease Oncogenic HPV infection common Cigarette smoking, other STDs, immunosuppression
Differentiated VIN	Unproven but likely precursor to most vulva squamous cell carcinoma Older, postmenopausal women Unicentric and unifocal disease Oncogenic HPV infection uncommon Associated with vulvar dermatologic conditions such as lichen sclerosus

CIS = carcinoma in situ; HPV = human papillomavirus; HSIL = high-grade squamous intraepithelial lesion; LSIL = low-grade squamous intraepithelial lesion; STD = sexually transmitted disease; VIN = vulvar intraepithelial neoplasia.

Diagnosis

Clinical Findings

VIN may be asymptomatic and discovered with routine gynecologic examinations or during evaluation of abnormal cervical or vaginal cytology results. No screening strategies are available for vulvar HSIL detection. When present, signs and symptoms

FIGURE 29-18 A. Extensive perineal and perianal extension of vulvar high-grade intraepithelial lesion (HSIL). **B.** Bulky lesion of differentiated vulvar intraepithelial neoplasia (VIN).

include itching, burning, and pain. Whereas high-grade lesions of the cervix and vagina are generally invisible without acetic acid application and use of a colposcope, clinically significant vulvar HSIL lesions are often visible without the aid of special techniques. Lesions vary widely in appearance but are usually sharply demarcated. They may be white, hyperkeratotic plaques; hyperpigmented lesions; or erythematous areas. Lesions may be raised or flat. Often, lesions appear bulky, resemble condylomata, and are multifocal with extensive involvement of the perineum (Fig. 29-18). Differentiated VIN is generally unifocal and may be associated with inflammatory dermatosis such as lichen sclerosis or lichen simplex chronicus of the adjacent skin. A lesion may appear as an ulcer, warty papule, or hyperkeratotic plaque.

To avoid diagnostic delay, most suspicious focal vulvar lesions are biopsied. Ulceration, surrounding induration, or inguinal adenopathy raises suspicion for invasive cancer. Other scenarios suspicious for VIN include enlarging lesions, warty lesions in postmenopausal or immune compromised women, and warts that appear atypical or persist despite topical therapies (American College of Obstetricians and Gynecologists, 2019).

Vulvoscopy

Histologic confirmation is necessary before vulvar HSIL or differentiated VIN are managed. Selection of the best location to biopsy is aided by magnification of the vulva, perineum, and perianal skin, usually with a colposcope. This examination is termed *vulvoscopy*. Alternatively, any good light source and a handheld magnifying lens can be used.

Vulvar epithelial changes are enhanced by applying a 3- to 5-percent acetic-acid-soaked gauze pad to the vulva for 5 minutes prior to vulvoscopy. Because vulvar epithelium is keratinized, application of acetic acid to achieve a useful visible effect requires longer time to develop. This is usually well tolerated but may cause pain or burning if comorbid vulvar irritation, ulceration, or fissures are present. Acetic acid accentuates surface topography and may reveal acetowhite lesions not seen grossly. Pigmented VIN lesions tend to turn a dusky gray due to hyperkeratosis, and vascular patterns are generally not seen. Normal vulvar tissue, particularly the inner, posterior labia minora, may turn diffusely acetowhite and should not be treated based on this appearance.

As an alternative, 1-percent toluidine blue, a nuclear stain, may help define lesions (Joura, 1998). However, because its use is technically more challenging and results are fraught with both false-positive and false-negative findings, this has been largely abandoned.

The most abnormal-appearing areas are biopsied, although necrotic areas often yield nondiagnostic findings and are avoided if possible. Biopsies measuring up to 6 mm in diameter can be obtained using a Keyes punch after provision of a local anesthetic injection (Fig. 4-2, p. 94). Biopsy sites measuring 4 mm or greater occasionally require suturing for hemostasis or cosmetic closure, especially on mucosal surfaces that stretch. Topical anesthetics can be applied several minutes prior to injection of local anesthesia to decrease discomfort. If lesions are close to the clitoral hood, general anesthesia is often warranted due to greater pain with injection of local anesthesia and increased tissue vascularity. Careful documentation, mapping of vulvar biopsy sites, and photographs can aid future management.

Management

Vulvar LSIL

Formerly termed VIN 1, vulvar LSIL encompasses flat condyloma and changes found from HPV effect. Vulvar LSIL is self-limited and not precancerous and is not treated unless symptomatic, such as with a gross condylomatous lesion (Bornstein, 2016).

Vulvar HSIL

Vulvar HSIL is a premalignant condition that can progress to vulvar cancer. Thus, all vulvar HSIL is treated, and standard options are local destruction or excision (American College of Obstetricians and Gynecologists, 2019). If occult invasion or cancer is not suspected, vulvar HSIL can be treated with laser ablation or with off-label use of topical imiquimod. Mucosal lesions (internal to the Hart line) tend to be more superficial,

whereas VIN involving hair-bearing areas of the vulva (external to the Hart line) may extend deeper into pilosebaceous units (Wright, 1992). VIN involves the pilosebaceous units in up to two thirds of cases, but it rarely exceeds 2.5 mm in depth from the epidermal surface (Shatz, 1989). This distance affects disease management, particularly if ablative procedures are considered. Regardless of the modality selected, treatment side effects are common and can include vulvar discomfort, poor wound healing, infection, and scarring that may result in chronic pain or dyspareunia. Thus, treatment objectives include: (1) excluding and preventing invasive disease, (2) preserving vulvar appearance and function, and (3) improving patient symptoms.

As allowed without damaging surrounding structures such as the clitoris or anus, *wide local excision (WLE)* with a gross surgical margin of 0.5 to 1 cm of normal tissue is preferred for large vulvar HSIL lesions, in which the possibility of invasive carcinoma cannot be excluded. Because disease recurrence is related to surgical margin status, intraoperative frozen-section histologic analysis of the specimen margins is advantageous (Friedrich, 1980; Jones, 2005). Hopkins and colleagues (2001) reported disease recurrence rates of 20 percent for cases with negative surgical margins but 40 percent for those with positive margins. Primary closure of a WLE should ideally be tension-free and may require referral to a specialist for plastic surgical techniques or skin grafting to minimize anatomic distortion, pain, and loss of function. Moreover, due to disease location, some patients are best treated by combined excisional and ablative procedures.

Laser ablation of vulvar HSIL provides good cosmetic results, but the depth of tissue destruction must be adjusted for hair-bearing areas. Laser treatment of vulvar HSIL requires full epithelial thickness cellular destruction. As CO_2 laser ablation does not allow evaluation of a surgical specimen, invasive carcinoma must be excluded by adequate biopsy beforehand. Laser is generally less disfiguring than WLE but can result in prolonged, painful healing. Preoperative counseling regarding anticipated postoperative results mirrors that for WLE. A Cochrane Review comparing surgical interventions for the treatment of vulvar HSIL concludes that surgical excision or laser vaporization is generally equally effective (Lawrie, 2016). Further, both interventions have an overall 50-percent chance of vulvar HSIL recurrence.

Cavitational ultrasonic surgical aspiration (CUSA) may be used to treat vulvar HSIL confined solely to non-hair-bearing vulvar skin. Ultrasound is used to cause cavitation and disruption of affected tissue, which is then aspirated and collected (Section 43-29, p. 1007). CUSA offers the advantages of laser, less scarring and pain than WLE, while additionally providing a pathologic specimen (von Gruenigen, 2007). However, the tissue specimen is fragmented and lacks the diagnostic accuracy of surgically excised tissue. One study evaluated CUSA in 37 patients with high-grade VIN and found an overall recurrence rate of 35 percent within a mean of 33 months (Miller, 2002).

Topical therapy can be considered if there is no concern for invasive cancer, the patient is able to self-administer the topical medication correctly, and the importance of compliance to follow-up visits is understood. No topical agent is FDA approved specifically for vulvar HSIL treatment, and use is considered off-label. Cidofovir is a cytosine analog with antiviral activity against a broad range of DNA viruses. Cidofovir cream must be specially compounded. Topical 5-FU is potentially caustic and teratogenic and is not a first-line choice for VIN treatment (National Cancer Institute, 2019b). The clinical efficacy of cidofovir and 5-FU creams has not been consistently demonstrated in clinical trials (American College of Obstetricians and Gynecologists, 2019). Topical imiquimod 5-percent has been found to be more effective than placebo in treating select vulvar HSIL lesions and has garnered the most interest for medical management (Lawrie, 2016). It has lower toxicity, and numerous case reports and two randomized trials report favorable regression rates of high-grade VIN (Mahto, 2010; van Seters, 2008). One Phase II study using imiquimod to treat high-grade VIN found a 77-percent response rate and 20-percent recurrence rate compared with a recurrence rate of 53 percent in a surgically treated cohort (Le, 2007). Currently, no studies establish the superiority of surgical or medical treatment of high-grade VIN.

Prognosis and Prevention

Case reports exist describing the invasive potential of untreated, high-grade VIN (Jones, 2005). Jones and associates (1994) reviewed the outcome of 113 patients with high-grade VIN. They found that 87 percent of untreated patients progressed to vulvar cancer, whereas only 3.8 percent of treated patients progressed to invasive carcinoma. Regardless of the treatment modality chosen, recurrence rates up to 50 percent are common, particularly in patients with multifocal disease or immune compromise (Lawrie, 2016). Indefinite surveillance for multifocal LAGT disease is recommended. Moreover, some consider high-grade VIN to be an indication for colposcopic evaluation of the cervix and vagina regardless of normal cervical or vaginal cytology. Although unproven, posttreatment surveillance consists of vulvar self-examination and careful office vulvar reevaluation at 6 and 12 months and annual vulvar inspection thereafter (American College of Obstetricians and Gynecologists, 2019).

For prevention, HPV vaccination lowers the risk for both vulvar LSIL and vulvar HSIL (American College of Obstetricians and Gynecologists, 2017). Smoking cessation and improving compromised immune status are others. As differentiated VIN may be found with vulvar dermatoses, treating these conditions may reduce cancer risk (Lee, 2015).

ANAL INTRAEPITHELIAL NEOPLASIA

Pathophysiology

In 2019, 5530 new anal cancers and 760 anal cancer deaths are predicted for U.S. women. Moreover, this relatively rare cancer's incidence and associated mortality rates have risen since 1975 (American Cancer Society, 2019a). Anal cancer is strongly associated with anal intraepithelial neoplasia (AIN) (Abbas, 2010; Palefsky, 1994). As with cervical cancer, hrHPV infection is strongly associated with and appears to be the causative

agent of most anal cancer, although anal cancers are rare in healthy women with only transient HPV infection (Lamme, 2014; Mosckicki, 2015; Sehnal, 2014). The causal relationship between HPV infection and anal cancer is supported by the finding that HPV is found in 88 percent of anal cancers (Wang, 2017). As with cervical cancers, HPV types 16 and 18 are the principal etiologic agents (Zbar, 2002). Concurrent HPV infection and related disease of the cervix and anal canal are common. In one analysis, cervical and anal HPV infections were highly correlated regardless of HIV status (Lin, 2019). Santoso and associates (2010) reported a 12-percent prevalence of biopsy-proven AIN in a group of women with HPV-related disease.

Anal HPV infection and its progressive potential in women are suspected to behave similarly to cervicovaginal lesions. Cervical and anal HPV lesions generally manifest at or near their highly susceptible squamocolumnar epithelial junctions. In the anal canal, this junction is called the *transition zone* (Goldstone, 2001). Anal disease is classified by the same cytologic and histologic nomenclature used to describe cervical disease. As adopted by the American College of Obstetricians and Gynecologists (2018b), the 2012 Lower Anogenital Squamous Terminology (LAST) Project nomenclature recommendation for squamous neoplasia throughout the anogenital tract replaces AIN 1 with the term *anal LSIL*, and AIN 2/3 with *anal HSIL* (Fig. 29-19) (Darragh, 2012).

Risk factors for AIN include persistent anal HPV infection, prior abnormal cervical cytology results, receptive anal intercourse, tobacco smoking, and prior other STDs, particularly HIV. Anal cancer and its likely precursor, anal HSIL, are increasing at higher rates in populations with HIV infection compared with those without HIV (Heard, 2015; Tandon, 2010). However, in one study of 251 women with HIV infection and 68 without, those without HIV infection had an 8-percent rate of any type of AIN and a 2-percent rate of anal HSIL (Holly, 2001).

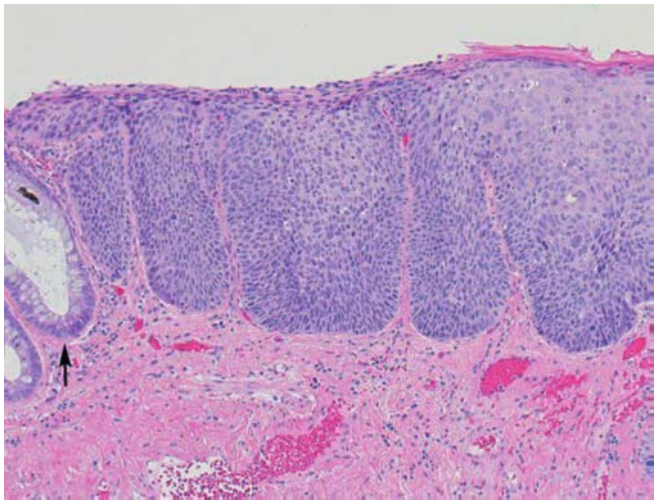

FIGURE 29-19 Anal intraepithelial neoplasia (AIN). In this example of AIN 3, the squamous epithelium has architectural disorder, nuclear pleomorphism, and markedly increased nucleus-to-cytoplasm ratios, with very little squamous maturation evident from base to surface. Mitoses are increased in number and located high in the epithelium. This biopsy was derived from the anorectal junctional area, and thus normal mucinous columnar epithelium lining rectal crypts is seen focally (*arrow*). (Reproduced with permission from Dr. Kelley Carrick.)

AIN progression to anal HSIL and cancer and its spontaneous regression are poorly understood. Many ongoing trials support the model of AIN progression to cancer. One 42-month surveillance study of 72 patients with AIN found that 11 percent of anal HSIL cases progressed to anal cancer (Watson, 2006).

Diagnosis

No data establish with certainty that the identification and treatment of AIN reduces anal cancer risk in the healthy woman. Currently, neither the American College of Obstetricians and Gynecologists nor the U.S. Preventive Services Task Force provides screening recommendations for AIN in women. Moscicki and associates (2015) summarized available literature on anal cancer, anal HSIL, and HPV infection in women. They proposed screening with digital anorectal examination for women at highest risk. Candidates are those with HIV infection, other immune compromising conditions, other HPV-related LAGT disease, or anal cancer symptoms (pain and bleeding). Other potential approaches for screening highest-risk women might include periodic testing with anal cytology, HPV testing, or anoscopy or with a combination of these. Some suggest that annual cervical and anal cytology should be offered to all women with HIV infection, but only if the infrastructure necessary to evaluate and manage abnormal cytology results and precancerous lesions is available (Palefsky, 2005; Panther, 2005). For the generalist, patients may be referred to tertiary care centers or colorectal surgeons.

Anal cytology as a screening test has uncertain efficacy for AIN and anal cancer (Nahas, 2009; Santoso, 2010). If used, anal cytology may be more sensitive using liquid-based preparations than conventional glass slides (Friedlander, 2004; Sherman, 1995). Sampling is obtained by inserting a Dacron swab or endocervical brush moistened with water or a small amount of water-based lubricant approximately 4 cm into the anal canal, presumably above the anal transition zone. The device is then withdrawn with a twirling motion while applying lateral pressure against the anal canal walls. The swab is then either swirled in the cytology solution to release exfoliated cells or smeared on a glass slide and fixed with isopropyl alcohol as with cervical cytology. Nothing per rectum is recommended 24 hours prior to an anal cytology test. Anal cytology may be reported using terminology and definitions of the Bethesda System for cervical cytology.

High-resolution anoscopy (HRA)-guided biopsy to identify histologic AIN uses illumination and magnification provided by a colposcope. HRA lacks general availability, is more challenging to perform than colposcopy for both patient and the provider, and requires special training. Acetic acid is applied to evaluate the anal canal in a manner similar to colposcopy (Fig. 29-20) (Jay, 1997). Anal neoplasia demonstrates colposcopic features similar to those of CIN, and analogous lesion grading and terminology are used. Biopsies are directed at the most abnormal areas. Some consider HRA to be the preferred tool for diagnosing AIN, but its role for primary screening or

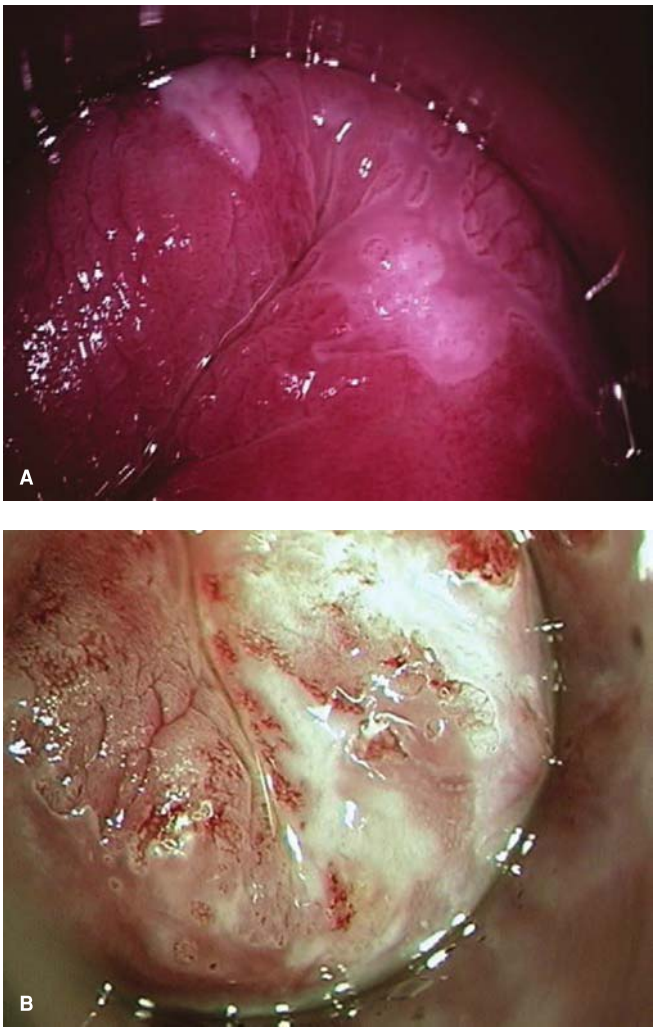

FIGURE 29-20 A. Translucent acetowhite lesion of low-grade anal intraepithelial neoplasia (AIN). **B.** Dense acetowhite lesion of high-grade AIN. (Reproduced with permission from Naomi Jay, RN NP PhD.)

for the evaluation of abnormal anal cytology results and anal cancer symptoms is not yet defined. It is presently available in a limited number of health centers.

Management

Some suggest that screening for and eliminating high-grade anal lesions may decrease the invasive anal cancer incidence (Santoso, 2010). However, in contrast to cervical neoplasia, the protective effect of treating anal cancer precursor lesions remains unproven. Thus, until more data are available, decisions regarding screening for and managing AIN should be shared by the provider and patient on an individual basis. Abnormal anal cytology results are best evaluated with high-resolution anoscopy. High-grade AIN lesions are referred to appropriate specialists for possible excision or ablative procedures.

Treatment is restricted to locally ablative or excisional procedures and topical therapies that eliminate individual high-grade intraepithelial lesions. Unlike the cervix, the entire anal squamocolumnar junction cannot be destroyed or removed due to potential associated morbidity. Biopsy-proven high-grade AIN lesions have been ablated using CO_2 laser, cryoablation, electrosurgical coagulation performed under general anesthesia, or infrared coagulation as an office procedure (Chang, 2002; Goldstone, 2005). Topically applied therapies that use imiquimod, 5-FU, or trichloroacetic acid are other unproven alternatives. Last, as prevention, the FDA (2010) has approved both the quadrivalent and nonavalent HPV vaccines for the prevention of anal cancer and precancerous lesions associated with select oncogenic HPV types in both males and females.

WOMEN WITH HIV INFECTION

These individuals have a high burden of HPV-associated LAGT disease. Up to 60 percent of Pap test results are abnormal, and up to 40 percent of cases have colposcopic evidence of dysplasia. Compared with rates in uninfected women, women with HIV infection show higher rates of both CIN and VIN (Ellerbrock, 2000; Spitzer, 1999; Wright, 1994). Moreover, abnormal cervical cytology and/or cervical HPV results raise risks for anal HPV infection and anal neoplasia (Heard, 2015; Tandon, 2010). The risks of all HPV-associated cancers of the vulva, vagina, and anus appear to rise during the period from 5 years before to 5 years after HIV seroconversion (Chaturvedi, 2009).

HIV infection influences LAGT disease prognosis. For example, during the early years of the AIDS epidemic, Maiman and colleagues (1990) observed a 100-percent mortality rate in women with HIV infection and cervical cancer compared with only a 37-percent rate in women affected by this cancer but not HIV. As a result, cervical cancer was designated as an AIDS-defining condition. Fortunately, women with HIV infection who receive regular screening and recommended follow-up for CIN experience the same incidence of invasive cervical cancer as do women without HIV (Massad, 2009).

Because of a significantly higher risk of developing SIL, cervical cancer screening guidelines for women with HIV differ from those of average risk women as described earlier (p. 631) (Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents, 2019). In addition, women with HIV may benefit from anal Pap screening (Palefsky, 2001). However, evidence-based screening recommendations for AIN and anal cancer are not yet available. Women with HIV infection are routinely questioned about anorectal symptoms such as pain or bleeding and are provided periodic digital rectal examinations.

The 2012 Consensus Guidelines recommend that Pap test abnormalities, including ASC-US, in women with HIV infection be managed as in the general population (Massad, 2013). However, the Centers for Disease Control and Prevention has questioned the utility of HPV testing for the triage of ASC-US in women with HIV and thus recommends that all women with ASC-US results be referred for colposcopy (Kaplan, 2009). Because women with HIV infection and CIN are often found to have extensive, multifocal dysplastic epithelial disease, any colposcopic examination includes inspection of the entire LAGT (Hillemanns, 1996; Tandon, 2010).

Women with HIV infection are at higher risk of disease persistence, recurrence, and progression after CIN or VIN treatment,

and poorer outcomes correlate with degree of immune suppression. Cryotherapy for CIN has a particularly high failure rate among treatment methods (Korn, 1996; Spitzer, 1999). Additionally, ablative modalities have a greater risk of obscuring occult invasive cancer in high-grade lesions. Cervical excisional procedures that include LEEP and CKC provide histologic confirmation and margins for evaluation. Although excisional therapy is effective for eradicating CIN in immune competent patients, the same treatment may be effective only in preventing progression to cancer in women with HIV (Heard, 2005).

The therapeutic benefits of antiretroviral therapy (ART) on HPV infection are poorly understood, and results are conflicting (Heard, 2004). To date, ART does not consistently improve the natural history of HPV-related disease. In fact, anal cancer rates in individuals with HIV infection have continued to rise over the past decade (De Vuyst, 2008; Tandon, 2010). Indeed, if ART does not alter the incidence or progression of HPV-related disease, individuals on ART may gain sufficient longevity to develop HPV-related epithelial cancers (de Sanjose, 2002).

Cervical cancer is the most common gynecologic cancer in women worldwide. Most of these cancers stem from infection with the human papillomavirus (HPV), although other host factors affect neoplastic progression following initial infection. Compared with other gynecologic malignancies, cervical cancer develops in a relatively younger population. Thus, screening for this neoplasia typically begins in young adulthood.

Most early cancers are asymptomatic. Thus, diagnosis usually follows histologic evaluation of biopsies taken during colposcopic examination or from a grossly abnormal cervix. This cancer is staged clinically, and this in turn directs treatment. In general, early-stage disease is effectively eradicated surgically. For advanced disease, chemoradiation is primarily selected. As expected, disease prognosis worsens with advancing tumor stage, and stage is the most important indicator of long-term survival.

Prevention lies mainly in identifying and treating women with high-grade dysplasia, and in HPV vaccination. Detailed in Chapter 29 (p. 628), regular screening is recommended and HPV vaccination is encouraged to lower future rates of cervical cancer.

INCIDENCE

Worldwide, cervical cancer is common, and it ranks fourth among all malignancies for women (World Health Organization, 2019). In 2018, global cervical cancer estimates include nearly 570,000 new cases and more than 311,000 deaths. In general, higher incidences are found in developing countries, and these countries contribute 85 percent of reported cases annually. In these populations, mortality rates are similarly higher (Torre, 2015). These incidence and survival disparities highlight successes achieved by long-term cervical cancer screening programs.

In the United States, cervical cancer is the third most common gynecologic cancer and the 11th most common solid malignant neoplasm among women. Women have a 1 in 132 lifetime risk of developing this cancer. In 2019, the American Cancer Society estimated 13,170 new cases and 4250 deaths from this malignancy (Siegel, 2019). Of U.S. women, black women and those in lower socioeconomic groups have the highest age-adjusted cervical cancer death rates, and Hispanic women have the highest incidence rates (Table 30-1). This trend is thought to stem mainly from financial and cultural characteristics affecting access to screening and treatment. The age at which cervical cancer develops is in general earlier than that of other gynecologic malignancies, and the median age at diagnosis is 50 years (Howlader, 2019).

RISKS

In addition to demographic differences, other risks may alter HPV acquisition or action. Notably, the greatest risk is the lack of regular cervical cancer screening (Abed, 2006; Leyden, 2005). Most communities adopting such screening have documented declines in this cancer's incidence (Jemal, 2006).

HPV is the primary etiologic infectious agent associated with cervical cancer (Ley, 1991; Schiffman, 1993). Although other sexually transmitted factors, including herpes simplex virus 2, may play a concurrent causative role, 99.7 percent of cervical cancers are associated with an oncogenic HPV subtype (Walboomers, 1999). In one study, 63 percent of invasive cervical cancer cases were attributable to HPV serotype 16. Serotype 18 was associated with 16 percent of invasive disease cases (Guan, 2012). Each of these serotypes can lead to either squamous cell carcinoma or adenocarcinoma of the cervix. However, HPV 16 is more commonly associated with squamous cell carcinoma of

TABLE 30-1. Cervical Cancer Age-Adjusted Incidence and Death Rates (per 100,000 women per year)

	All Races	White	Black	Asian American & Pacific Islander	American Indian & Alaskan Native	Hispanic
Incidence	7.3	7.2	8.7	6.4	7.9	9.3
Death	2.3	2.2	3.5	1.7	1.8	2.6

Based on cases diagnosed during 2012 through 2016 from 21 geographic areas in the Surveillance, Epidemiology and End Results (SEER) Program.
Data from Howlader, 2019.

the cervix, whereas HPV 18 is a risk factor for cervical adenocarcinoma (Bulk, 2006).

Of other risks, lower educational attainment, older age, obesity, smoking, and neighborhood poverty are independently related to lower rates of cervical cancer screening. Specifically, those living in impoverished neighborhoods have limited access to testing and may benefit from screening outreach programs (Datta, 2006).

Cigarette smoking, both active and passive, raises cervical cancer risk. Among HPV-infected women, current and former smokers have a two- to threefold greater incidence of high-grade squamous intraepithelial lesion (HSIL) or invasive cancer. Passive smoking is also associated with higher risk, but to a lesser extent (Trimble, 2005). The mechanism underlying the association between smoking and this cancer is unclear. Smoking may alter HPV infection in those who smoke. For example, "ever smoking" is associated with reduced clearance of high-risk HPV (Koshiol, 2006; Plummer, 2003). Tobacco smoke may also modify viral oncoprotein expression in cells in which the HPV is not integrated into the host genome (Wei, 2014).

Parity has a significant association with cervical cancer. Specifically, women with seven prior full-term pregnancies have an approximately fourfold risk, and those with one or two have a twofold risk compared with nulliparas (Muñoz, 2002).

Long-term combination oral contraceptive (COC) use is another factor. In women who are positive for cervical HPV DNA and who use COCs, cervical carcinoma rates rise by up to fourfold compared with women who are HPV-positive and never users (Moreno, 2002). Additionally, current COC users and women who are within 9 years of use have a significantly higher risk of developing both squamous cell and adenocarcinoma of the cervix (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006). Encouragingly, the relative risk to COC users appears to decline after cessation. Data from 24 epidemiologic studies showed that by 10 or more years following COC cessation, cervical cancer risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007).

Sexual activity logically has an association because HPV is sexually transmitted. Having more than six lifetime sexual partners elevates the relative risk of cervical cancer. Similarly, an early age of first intercourse before age 20 confers a greater risk of developing this malignancy. Intercourse after age 21 only shows a trend toward an elevated risk. Moreover, abstinence from sexual activity and barrier protection during sexual intercourse lowers cervical cancer incidence (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006).

Immunosuppressed women have an increased risk of developing cervical cancer. Cervical cancer is an acquired immune deficiency syndrome (AIDS)-defining illness, and the standardized incidence ratio (SIR) of developing this cancer in women with HIV is 5.82. For transplant recipients, the SIR is 2.01 for this malignancy (Grulich, 2007). Women with autoimmune diseases who use immunosuppressants do not appear to have an greater cervical cancer risk, except for azathioprine users (Dugue, 2015).

PATHOPHYSIOLOGY

Tumorigenesis

Most women readily clear HPV, but those with persistent infection may develop preinvasive dysplastic cervical lesions. From such lesions, squamous cell carcinoma of the cervix typically arises at the squamocolumnar junction (Bosch, 2002). In general, progression from dysplasia to invasive cancer requires several years, although times can vary widely. The molecular alterations involved with cervical carcinogenesis are complex and not fully understood. Carcinogenesis currently is suspected to result from the interactive effects among environmental insults, host immunity, and somatic-cell genomic variations (Helt, 2002; Jones, 1997, 2006; Wentzensen, 2004).

Increasing evidence suggests that HPV oncoproteins may be a critical component of continued cancer cell proliferation (Mantovani, 1999; Munger, 2001). Unlike low-risk serotypes, oncogenic HPV serotypes can integrate into human DNA (Fig. 30-1). As a result, with infection, oncogenic HPV's early replication proteins E1 and E2 enable the virus to replicate within cervical cells. These proteins are expressed at high levels early in HPV infection. They can lead to cytologic changes detected as low-grade squamous intraepithelial (LSIL) cytologic findings from Pap testing.

Amplification of viral replication and subsequent transformation of normal cells into tumor cells may follow (Mantovani, 1999). Specifically, the viral gene products E6 and E7 oncoproteins are implicated in this transformation (Fig. 30-2). E7 protein binds to the retinoblastoma (Rb) tumor suppressor protein, whereas E6 binds to the p53 tumor suppressor protein. In both instances, binding leads to degradation of these suppressor proteins. The E6 effect of p53 degradation is well studied and linked with the proliferation and immortalization of cervical cells (Jones, 1997, 2006; Mantovani, 1999; Munger, 2001).

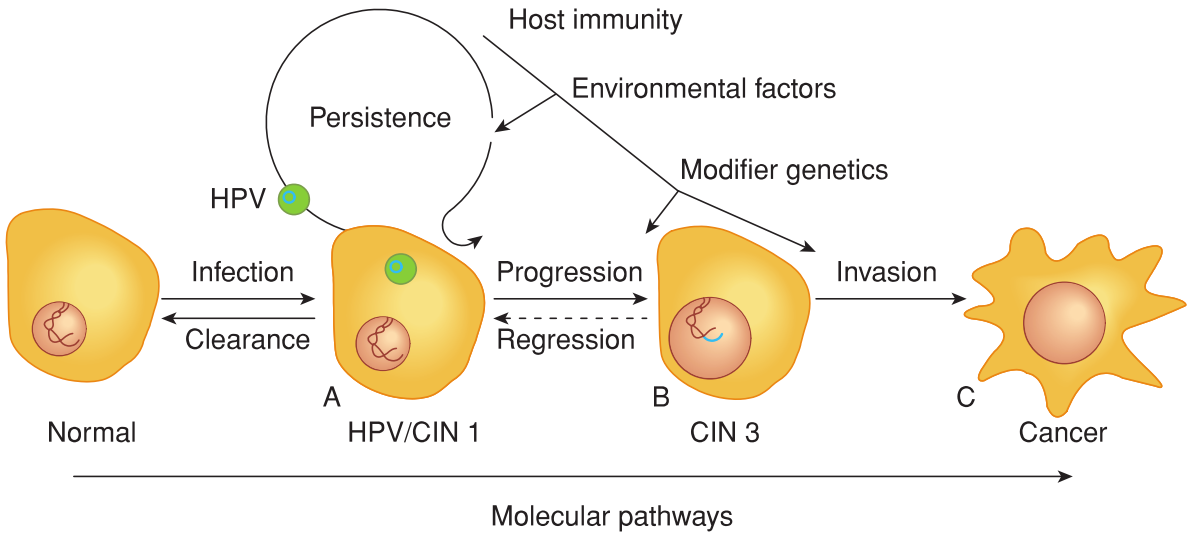

FIGURE 30-1 Critical end points lie on the spectrum of cervical dysplasia. **A.** This initial point shows the cell at risk due to active HPV infection. The HPV genome (*blue ring*) exists as a plasmid, separate from the host DNA. **B.** The clinically relevant preinvasive lesion, cervical intraepithelial neoplasia 3 (CIN 3) or carcinoma in situ (CIS), is an intermediate stage in cervical cancer development. The HPV genome has become integrated into the host DNA, resulting in increased proliferative ability. **C.** Interactive effects between environmental insults, host immunity, and somatic cell genomic variations lead to invasive cervical cancer.

Tumor Spread

Following tumorigenesis, the pattern of local growth may be exophytic if a cancer arises from the ectocervix, or may be endophytic if it arises from the endocervical canal (Fig. 30-3). Lesions lower in the canal and on the ectocervix are more likely to be clinically visible during physical examination. Alternatively, growth may be infiltrative, and in these cases, ulcerated lesions are common if necrosis accompanies this growth. As primary lesions enlarge and lymphatic involvement progresses, local invasion increases and will eventually become extensive.

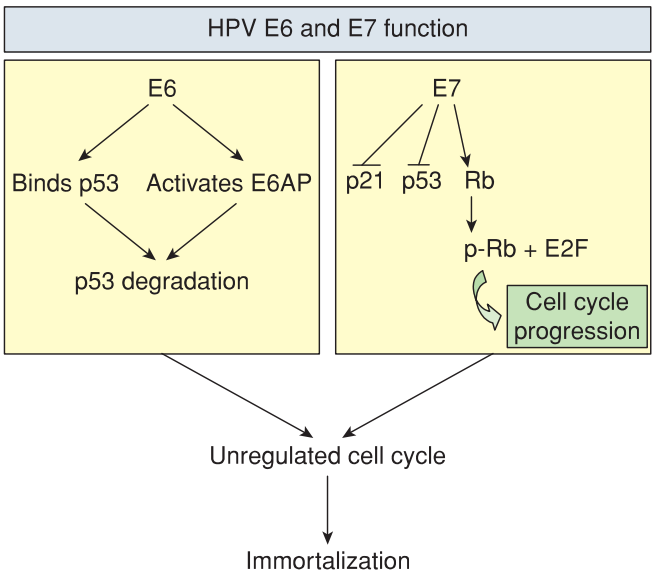

FIGURE 30-2 Effects of E6 and E7 oncoproteins. On the left, viral oncoprotein E6 directly binds p53 and also activates E6AP to degrade p53 tumor suppressor protein. On the right, E7 oncoprotein phosphorylates retinoblastoma tumor suppressor protein, resulting in release of E2F transcription factors, which are involved in cell cycle progression. E7 also downregulates p21 tumor suppressor protein production and subverts p53 function. The cumulative effect of E6 and E7 oncoproteins eventually results in cell cycle alteration, promoting uncontrolled cell proliferation.

Lymphatic Spread

Lymph Node Groups. The pattern of tumor spread typically follows cervical lymphatic drainage. Thus, familiarity with this drainage aids understanding the surgical steps of radical hysterectomy performed for this cancer (Section 46-1, p. 1160). The cervix has a rich network of lymphatics, which follow the course of the uterine artery (Fig. 30-4). These channels drain principally into the paracervical and parametrial lymph nodes. These lymph nodes are clinically important and thus are removed as part of parametrial resection during radical hysterectomy. From the parametrial and paracervical nodes, lymph subsequently flows into the obturator lymph nodes and into the internal, external, common iliac lymph nodes, and ultimately the paraaortic lymph nodes. Accordingly, pelvic and paraaortic lymph nodes are also traditionally removed concurrently with radical hysterectomy. In contrast, lymphatic channels from the posterior cervix course through the rectal pillars and the uterosacral ligaments to the rectal lymph nodes. These nodes also are encountered and are removed during the extended resection of the uterosacral ligaments that is characteristic of radical hysterectomy.

Lymphovascular Space Involvement. As tumor invades deeper into the stroma, it enters blood capillaries and lymphatic channels (Fig. 30-5). Termed *lymphovascular space involvement (LVSI)*, this type of invasive growth is not included in the clinical staging of cervical cancer. However, its presence is regarded as a poor prognostic indicator, especially in early-stage cervical

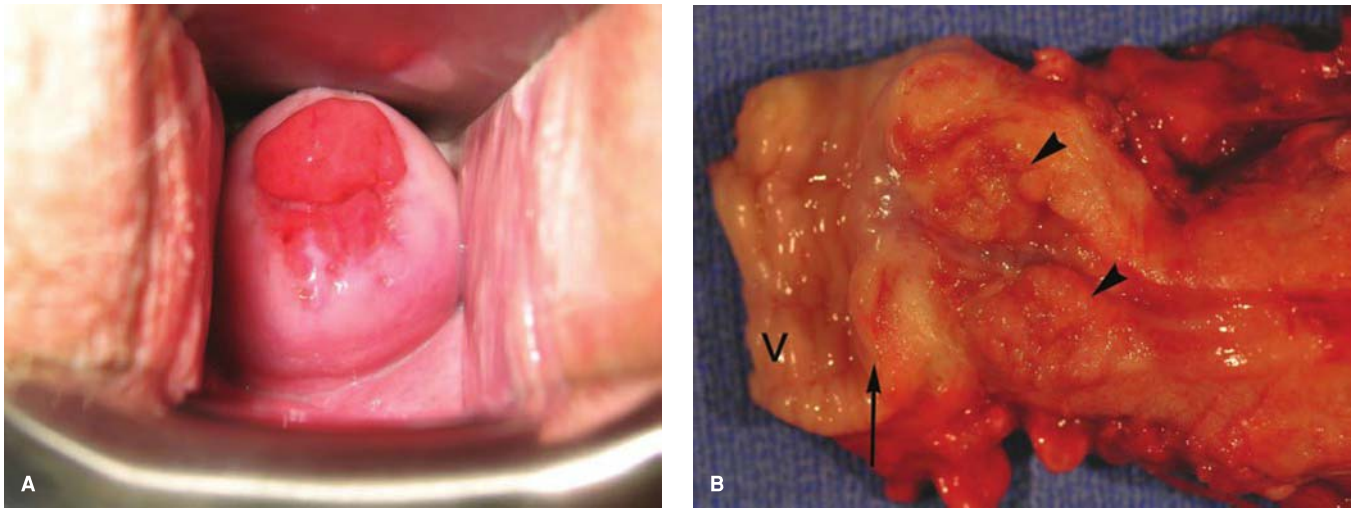

FIGURE 30-3 Cervical adenocarcinoma. **A.** Invasive cancer originating from the endocervix. (Reproduced with permission from Dr. David Miller.) **B.** Exophytic growth of cervical adenocarcinoma into the endocervical canal (*arrowheads*). In this radical hysterectomy specimen, proximal vagina (*V*) is excised with the cervix, and an arrow marks the ectocervix.

cancers. Thus, the presence of LVSI often requires tailoring the planned surgical procedure and adjuvant radiation treatment.

Local and Distant Tumor Extension

With extension through the parametria to the pelvic sidewall, ureteral blockage frequently develops, resulting in hydronephrosis (Fig. 30-6). Additionally, the bladder may be invaded by direct

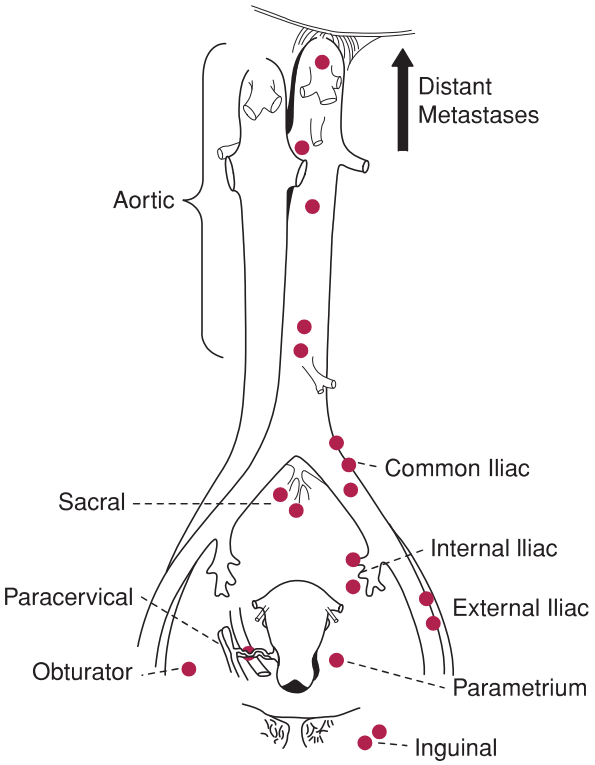

FIGURE 30-4 Lymphatic drainage of the cervix. The parametrial lymph nodes are removed during radical hysterectomy. Pelvic and paraaortic nodes also may be removed by lymphadenectomy. Melanoma

Squamous cell carcinomas represent 70% of all cervical cancer, and adenocarcinomas account for 25% of cervical cancers. The other cell types are rare.

tumor extension through the vesicouterine ligaments (bladder pillars). The rectum is invaded less often because it is anatomically separated from cervix by the posterior cul-de-sac. Distant metastasis results from hematogenous dissemination, and the lungs, ovaries, liver, and bone are the most frequently affected.

HISTOLOGIC TYPES

Squamous Cell Carcinoma

The two most common histologic subtypes of cervical cancer are squamous cell and adenocarcinoma (Table 30-2). Of these, squamous cell tumors predominate, make up approximately 70 percent of all cervical cancers, and arise from the ectocervix. Over the past 30 years, the incidence of squamous cell cancers has declined, whereas that of cervical adenocarcinoma has risen. These changes may be attributed to an improved method of screening for early squamous lesions of the cervix (Vizcaino, 2000). Squamous cell carcinomas can be subdivided into keratinizing and nonkeratinizing carcinomas (Fig. 30-7).

Adenocarcinomas

Adenocarcinomas are a group of cervical cancers composed of the subtypes listed in Table 30-2. Adenocarcinomas make up

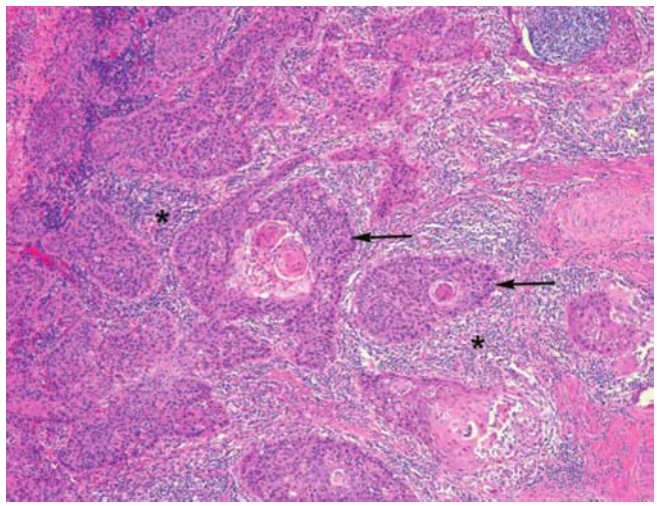

FIGURE 30-7 Invasive cervical squamous cell carcinoma. Irregular nests of malignant squamoid cells (*arrows*) invade the cervical stroma haphazardly and are accompanied by a brisk lymphocytic response (*asterisks*). Some of the tumor nests in this moderately differentiated example have eosinophilic keratin pearls at their center, a classic diagnostic feature of squamous cell carcinoma. (Reproduced with permission from Dr. Raheela Ashfaq.)

25 percent of cervical cancers and arise from the endocervical mucus-producing columnar cells. Because of this origin within the endocervix, adenocarcinomas are often occult and may be advanced before becoming clinically evident. They often give the cervix a palpable barrel shape during pelvic examination.

Adenocarcinomas exhibit various histologic patterns. Of these, *mucinous adenocarcinomas* are the most common and are subdivided as shown in Table 30-2. The mucinous endocervical type retains resemblance to normal endocervical tissue (Fig. 30-8). In

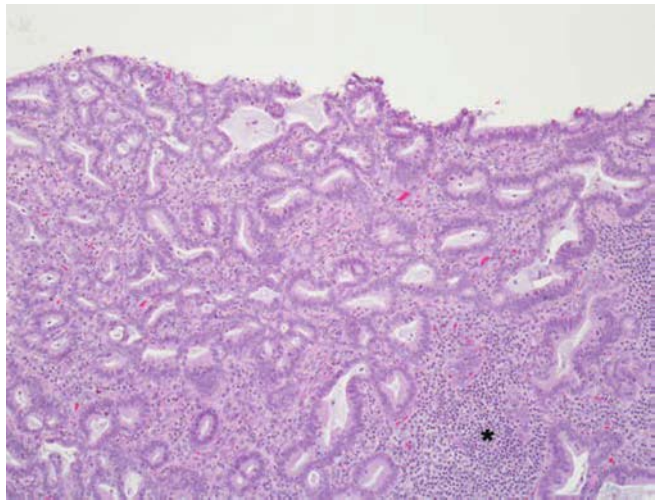

FIGURE 30-8 Invasive endocervical adenocarcinoma. This endocervical adenocarcinoma of usual (HPV-related) type is characterized by columnar, relatively mucin-poor cells with stratified, atypical nuclei and brisk mitotic activity. Tumor cells form glands that resemble native endocervical glands but invade the stroma haphazardly. A chronic inflammatory infiltrate is present at right (*asterisk*). (Reproduced with permission from Dr. Kelley Carrick.)

contrast, the intestinal type resembles intestinal cells and may include goblet cells. *Minimal deviation adenocarcinoma,* also known as *adenoma malignum*, is characterized by cytologically bland glands that are abnormal in size and shape. These tumors contain a greater number of glands positioned at a deeper level than normal endocervical glands. Women with Peutz-Jeghers syndrome are at higher risk of developing adenoma malignum. *Villoglandular adenocarcinomas* are made up of surface papillae. *Endometrioid adenocarcinomas* are the second most frequently identified and display glands resembling those of the endometrium. *Serous carcinoma* is identical to serous carcinomas of the ovaries or uterus and is rare. *Clear cell adenocarcinoma* accounts for less than 5 percent of cervical adenocarcinomas and is named for its clear cytoplasm (Jaworski, 2009). Rarely, adenocarcinomas arise in mesonephric remnants in the cervix, termed *mesonephric adenocarcinomas*.

Prognosis Comparison

Evidence describing the prognosis of squamous cell carcinoma compared with that of adenocarcinoma is contradictory. For stage IB and IIA cervical cancer, one study showed a statistically significant lower overall survival rate in those with adenocarcinoma compared with women with squamous cell carcinoma (Landoni, 1997). However, the Gynecologic Oncology Group (GOG) found in a subsequent study that overall survival rates in women with stage IB squamous and adenocarcinomas of the cervix are similar (Look, 1996). For advanced-stage (stage IIB to IVA) cancers, evidence suggests that cervical adenocarcinomas may portend a poorer overall survival rate compared with similarly staged squamous cell carcinomas (Eifel, 1990; Lea, 2002). The 2006 International Federation of Obstetricians and Gynecologists (FIGO) annual report, which reported on more than 11,000 squamous cell carcinomas and 1613 adenocarcinomas, demonstrated that women with adenocarcinomas have worse overall survival rates at every stage compared with those with squamous cell carcinoma (Quinn, 2006). In sum, evidence suggests that adenocarcinoma of the cervix is a high-risk cell type.

Other Tumor Types

Mixed cervical carcinomas are rare. Of these, *adenosquamous carcinomas* do not differ grossly from adenocarcinomas of the cervix. The squamous component is poorly differentiated and shows little keratinization. *Glassy cell carcinoma* describes a form of poorly differentiated adenosquamous carcinoma in which cells display cytoplasm with a ground-glass appearance.

Neuroendocrine tumors of the cervix include large cell and small cell tumors. These rare tumors are highly aggressive, and even early-stage cancers have a relatively low disease-free survival rate despite treatment with radical hysterectomy and adjuvant chemotherapy (Gardner, 2011; Viswanathan, 2004). Often, neuroendocrine markers, including chromogranin, synaptophysin, and CD56, are used to confirm the diagnosis. Uncommonly, endocrine and paraendocrine tumors are associated with these neuroendocrine tumors.

Of other rare types, the cervix may be the site of sarcomas, malignant lymphomas, and melanomas. Cervical leiomyosarcomas and cervical stromal sarcomas have a poor prognosis, similar to that for uterine sarcomas. Melanomas often present as ulcerated blue or black nodules and also have a poor prognosis.

DIAGNOSIS

Symptoms

Some women diagnosed with this cancer are asymptomatic. In others, early-stage cervical cancer may create a watery, blood-tinged vaginal discharge. Intermittent vaginal bleeding that follows coitus or douching also can be noted. As a malignancy enlarges, bleeding typically intensifies, and occasionally, a woman presents with uncontrolled hemorrhage from a tumor bed. In such cases, bleeding can often be controlled with a combination of Monsel paste (ferric subsulfate) and vaginal packing. Topical acetone can also be used to obtain hemostasis, especially in cases refractory to Monsel paste (Patsner, 1993). Burning from acetone makes it a less desirable choice than Monsel paste. With vaginal packing, the patient ideally remains at bed rest, and a Foley catheter is concurrently inserted to drain the bladder. The pack may interfere with normal voiding, and the catheter also allows for accurate monitoring of urine output during volume resuscitation. If bleeding continues, emergent radiation can be delivered. Alternatively, internal iliac artery embolization or ligation can be performed in cases of refractory hemorrhage. However, caution is used for these latter two options, as tumor oxygenation is impaired if the blood supply is occluded. Radiation therapy is a primary component of advanced-stage cancer, and as noted in Chapter 28 (p. 614), radiation's effects are diminished in low-oxygen environments. This can translate into worsening disease-specific survival rates (Kapp, 2005). In those with significant bleeding, hemodynamic support of the patient follows that described in Chapter 40 (p. 862).

Physical Examination

Most women with this cancer have normal general physical examination findings. In those with suspected cervical cancer, a thorough external genital and vaginal examination is performed. Because HPV is a shared risk factor for cervical, vaginal, vulvar, and anal cancers, concomitant lesions are sought. With speculum examination, the cervix can appear grossly normal if cancer is microinvasive. Visible disease displays varied appearances. Lesions may be exophytic or endophytic growth; a polypoid mass, papillary tissue, or barrel-shaped cervix; a cervical ulceration or granular mass; or necrotic tissue. A watery, purulent, or bloody discharge also can be seen. For this reason, cervical cancer may mirror the appearance of a cervical leiomyoma, cervical polyp, vaginitis, cervical eversion, cervicitis, threatened abortion, placenta previa, cervical pregnancy, condyloma acuminata, herpetic ulcer, chancre, or a prolapsing uterine leiomyoma, polyp, or sarcoma.

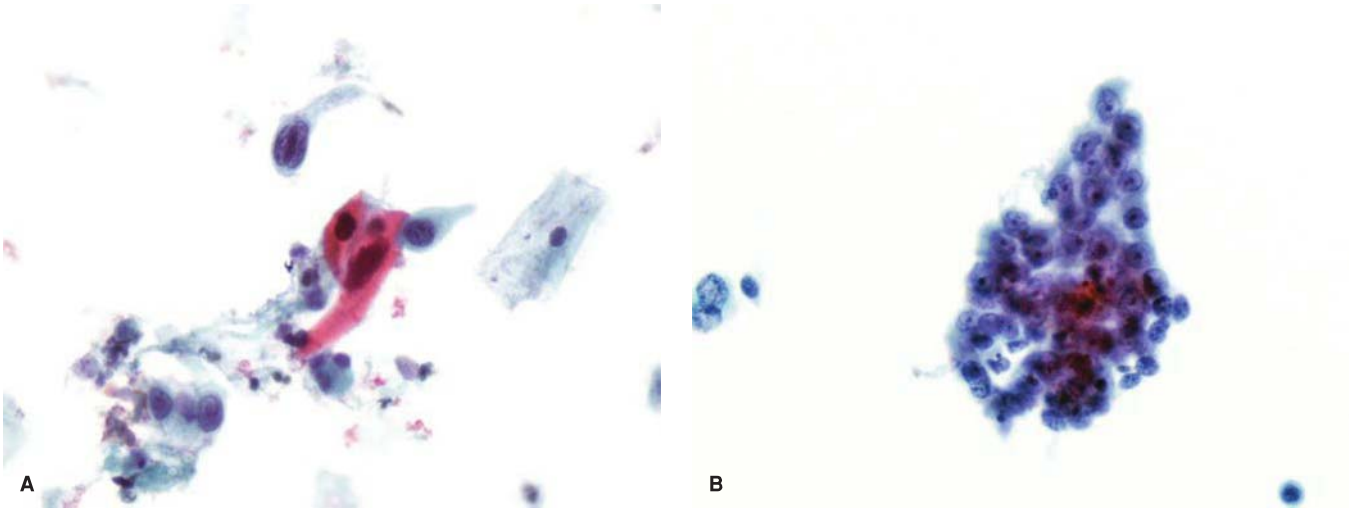

FIGURE 30-9 A. Pap smear, squamous cell carcinoma. Some show spindled tumor cells and/or cytoplasmic keratinization, as evidenced by dense orangeophilic cytoplasm. **B.** Pap smear, endocervical adenocarcinoma. This shows malignant cytologic features including nuclear pleomorphism, nuclear membrane abnormalities, and nucleolar prominence. Cytoplasm tends to be more delicate than in squamous carcinoma and may contain mucin. (Reproduced with permission from Ann Marie West, MBA, CT[ASCP].)

During bimanual examination, a clinician may palpate an enlarged uterus resulting from tumor invasion and growth. Alternatively, hematometra or pyometra may expand the endometrial cavity following obstruction of fluid egress by a primary cervical cancer. In this case, the uterus may feel enlarged and boggy. Advanced cervical cancer cases can extend into the vagina, and disease extent can be appreciated during anterior vaginal wall palpation or during rectovaginal examination. With posterior spread, palpation of the rectovaginal septum between the index and middle finger of an examiner's hand reveals a thick, hard, irregular septum. The proximal posterior vaginal wall is most commonly invaded. In addition, during digital rectal examination, parametrial, uterosacral, and pelvic sidewall involvement can be appreciated. Either one or both parametria may be invaded, and involved tissues feel thick, irregular, firm, and less mobile. A fixed mass indicates that tumor has probably extended to the pelvic sidewalls. However, a central lesion can become as large as 8 to 10 cm in diameter before reaching the sidewall.

With advancing disease, enlarged supraclavicular or inguinal lymphadenopathy suggest lymphatic tumor spread. Lower extremity edema and low back pain, often radiating down the posterior leg, may reflect compression of the sciatic nerve root, lymphatics, veins, or ureter by an expanding tumor. With ureteral obstruction, hydronephrosis and uremia can follow and may occasionally be the initial presenting finding. In these cases, ureteral stenting or percutaneous nephrostomy tube insertion are usually required. Kidney function is ideally preserved for chemotherapy. Additionally, with tumor invasion into the bladder or rectum, hematuria and/or vesicovaginal or rectovaginal fistula may be found.

Papanicolaou Test and Cervical Biopsy

Histologic evaluation of cervical biopsy is the primary tool to diagnose cervical cancer. Although Papanicolaou (Pap) tests are performed extensively to screen for this cancer, this test does not always detect cervical cancer. Specifically, Pap testing has only a 53- to 80-percent sensitivity for detecting high-grade lesions on any given single test (Agorastos, 2015; Benoit, 1984; Soost, 1991). Thus, the preventive power of Pap testing lies in regular serial screening (Fig. 30-9). Moreover, in women who have stage I cervical cancer, only 30 to 50 percent of single cytologic smears obtained are read as positive for cancer (Benoit, 1984). Hence, Pap testing alone for evaluation of a suspicious lesion is discouraged. Instead, these lesions are directly biopsied with Tischler biopsy forceps or a Kevorkian curette (Fig. 29-15, p. 637). When possible, biopsies are taken from the tumor periphery, as central portions often contain only necrotic tissue, which will fail to yield a histologic diagnosis. Moreover, biopsies ideally include underlying stroma, so that invasion, if present, can be assessed.

If abnormal Pap testing results are noted, colposcopy is often performed, and adequate cervical and endocervical biopsies are obtained. In some cases, cold-knife conization is needed for this. Indications for colposcopy and conization are outlined in Chapter 29, and cervical punch biopsies or conization specimens are the most accurate for allowing assessment of cervical cancer invasion. Both sample types typically contain underlying stroma and enable differentiation between invasive and in situ carcinomas. For this determination, conization specimens provide a larger tissue sample and are most helpful. However, the diagnostic value of conization is balanced against its higher short- and long-term risks compared with punch biopsy.

STAGING

The staging system widely used for cervical cancer is that developed by the International Federation of Gynecologists and Obstetricians (FIGO) in collaboration with the World Health Organization (WHO) and the International Union Against

TABLE 30-3. Clinical Stages of Cervical Cancer (FIGO, Revised 2018)

Stage	Characteristics[a]
0	**Carcinoma in situ, cervical intraepithelial lesion (CIN) 3**
I	**Carcinoma is strictly confined to cervix (extension to corpus should be disregarded)**
IA	Microscopic lesion, invasion is limited to measured stromal invasion with a maximum depth <5 mm
IA1	Measured invasion of stroma <3 mm in depth
IA2	Measured invasion of stroma ≥3 mm and <5 mm in depth
IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA
IB1	Invasive carcinoma <2 cm in greatest dimension
IB2	Invasive carcinoma ≥2 cm and <4 cm in greatest dimension
IB3	Invasive ≥4 cm in greatest dimension
II	**Carcinoma extends beyond uterus but has not extended to pelvic wall; it involves vagina, but not as far as the lower third**
IIA	No obvious parametrial invasion
IIA1	Invasive carcinoma <4 cm in size
IIA2	Invasive carcinoma ≥4 cm in size
IIB	Obvious parametrial involvement
III	**Carcinoma has extended to the pelvic wall; on rectal examination there is no cancer-free space between tumor and pelvic wall; tumor involves lower third of vagina; all cases with hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to another cause; involves pelvic and/or para-aortic lymph nodes[b]**
IIIA	No extension to pelvic wall, but involvement of lower third of vagina
IIIB	Extension to pelvic wall, or hydronephrosis or nonfunctioning kidney due to tumor
IIIC1	Pelvic lymph node metastasis only
IIIC2	Paraaortic lymph node metastasis
IV	**Carcinoma has extended beyond true pelvis or has clinically involved mucosa of bladder or rectum**
IVA	Spread of growth to adjacent pelvic organs
IVB	Spread to distant organs

FIGO = International Federation of Obstetricians and Gynecologists.
[a]Histology and imaging can supplement clinical findings in all stages with respect to tumor size and extent.
[b]Adding documentation of p (pathology) and r (imaging) to indicate method of stage assignment to stage IIIC. The type of imaging modality or pathologic technique should be notated.

Cancer (UICC). Cervical cancer staging was updated in 2018 and is detailed in Table 30-3 and Figure 30-10. Historically, cervical cancer has been staged clinically. The current staging system now incorporates radiologic and surgical evaluation (Bhatla, 2019). Allowable components of clinical staging are cold-knife conization, pelvic examination under anesthesia, cystoscopy, proctoscopy, chest radiograph, and intravenous pyelogram (or this portion of the computed tomography [CT] scan can be used). Table 30-4 lists the role of these elements and also contains radiologic and surgical assessments now incorporated in current staging. The table also describes laboratory tests that are not a part of formal staging but that may contribute additional information. Bullous edema is not sufficient for the diagnosis of bladder involvement, and this involvement must be biopsy proven. Lymph node metastasis is now included in staging. In this chapter, *early-stage disease* refers to FIGO stages I through IIA. The term *advanced-stage disease* describes stages IIB and higher.

Within each gynecologic chapter in this text, staging of each cancer type (cervix, vulva, vagina, uterus, ovary) will be presented. FIGO classification is used for gynecologic cancers. In contrast, the American Joint Committee on Cancer (AJCC) developed the *TNM Staging System*, which is based on the extent of the tumor (T), the extent of spread to the lymph nodes (N), and the presence of metastasis (M).

RADIOLOGIC IMAGING

Imaging is now incorporated into FIGO staging, and accurate evaluation is critical to appropriate treatment planning. For example, early-stage tumors may be treated surgically, whereas more advanced tumors require radiation and/or chemotherapy. Imaging results can tailor treatment for an individual. Lymph node metastases worsen patient prognosis and may be identified with imaging. Thus, radiologic tools such as CT scanning, magnetic resonance (MR) imaging, or positron emission tomography (PET) scanning are commonly used as adjuncts in initial cervical cancer evaluation. PET/CT is commonly used for patients with suspected IB and higher stages.

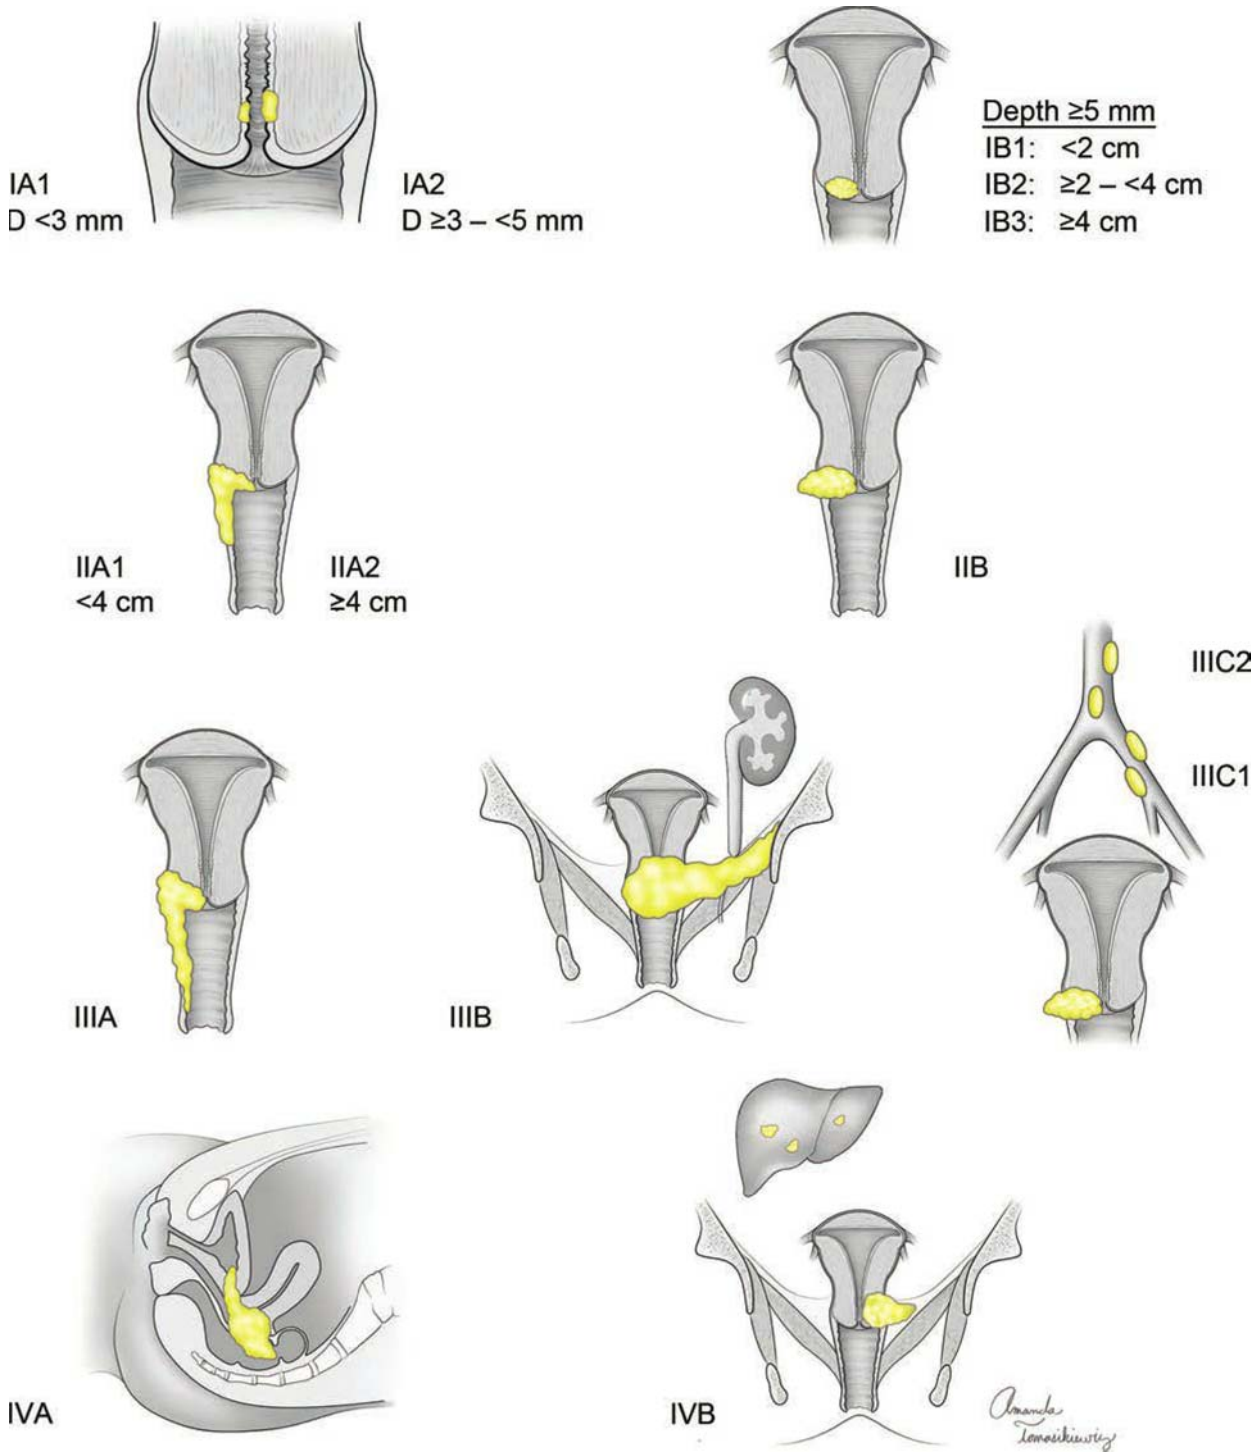

FIGURE 30-10 International Federation of Gynecologists and Obstetricians (FIGO) stages of cervical cancer.

Magnetic Resonance Imaging

For defining anatomy, this high-resolution imaging tool offers superior contrast resolution at soft-tissue interfaces. Thus, MR imaging effectively measures tumor size, delineates cervical tumor boundaries, and identifies surrounding bladder, rectal, or parametrial invasion. Unfortunately, MR imaging is less accurate for diagnosing microscopic or deep cervical stromal invasion or identifying minimal parametrial extension (Mitchell, 2006). These particular distinctions are important as both stromal and parametrial invasion may affect suitability for a given planned treatment. In addition, false-negative findings occur with small volumes of disease and with tissue foci in which cancer cannot be differentiated from scar or necrosis. In these cases, PET scanning identifies metabolic rather than anatomic changes and can be a complementary tool.

For primary cervical cancer, MR imaging is superior to CT for determining carcinoma size, local tumor extension, and lymph node involvement (Bipat, 2003; Mitchell, 2006; Subak, 1995). MR imaging is often preferred for patients being considered for fertility-sparing radical trachelectomy (Abu-Rustum,

TABLE 30-4. Testing Used During Cervical Cancer Evaluation

Testing	To Identify:
Laboratory	
CBC	Anemia
Urinalysis	Hematuria
Chemistry profile	Electrolyte abnormality
Liver function	Liver metastasis
Creatinine/BUN	Renal impairment or obstruction
Radiologic	
Chest radiograph	Lung metastasis
IVP	Hydronephrosis
CT scan (abdominopelvic)	Nodal or distant organ metastasis; hydronephrosis
MR imaging	Local parametrial invasion; nodal metastasis; tumor size
PET scan	Nodal or distant organ metastasis
Procedural	
Cystoscopy	Bladder tumor invasion
Proctoscopy	Rectal tumor invasion
EUA	Extent of pelvic tumor spread; clinical staging
Lymph node evaluation	Presence of lymph node metastases

BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; EUA = examination under anesthesia; IVP = intravenous pyelogram; MR = magnetic resonance; PET = positron emission tomography. Lymph node evaluation can include sentinel lymph node biopsy, removal of suspicious lymph nodes, or lymphadenectomy.

2008; Olawaiye, 2009). Overall, however, both MR imaging and CT perform similarly in cervical cancer (Hricak, 2005).

Computed Tomography

This is the most widely used imaging tool for the assessment of nodal involvement and distant metastatic disease. It offers high-resolution depiction of anatomy, especially when used with contrast. CT scanning is obtained in many women with cervical cancer to evaluate tumor size and bulky extension beyond the cervix. CT can also aid detection of enlarged lymph nodes, ureteral obstruction, or distant metastasis (Follen, 2003).

However, CT has limitations similar to MR imaging. CT is not accurate for assessing subtle parametrial invasion or deep cervical stromal invasion because of its poor soft-tissue contrast resolution. CT is also limited by its inability to detect small-volume metastatic involvement in normal-size lymph nodes. Moreover, internal node architecture is often poorly defined. This makes distinction between reactive lymph node hyperplasia and true metastatic disease difficult.

Positron Emission Tomography

This nuclear medicine imaging technique creates an image of functional processes within the body. With FDG-PET, a radiolabeled analogue of glucose, fluorodeoxyglucose (FDG), is injected intravenously and is taken up by metabolically active cells such as tumor cells. PET provides a poor depiction of detailed anatomy, thus scans are frequently read side-by-side with CT scans. The combination allows correlation of metabolic and anatomic data. As a result, current PET scanners are now commonly integrated with CT scanners, and the two scans can be performed during the same session (Fig. 2-33, p. 51).

FDG-PET is superior to CT or MR imaging for lymph node metastasis identification (Belhocine, 2002; Havrilesky, 2005; Selman, 2008). However, PET is insensitive for lymphatic metastasis <5 mm. Moreover, its role in early-stage smaller, resectable tumors is limited (Sironi, 2006; Wright, 2005). PET scans can be useful in planning radiation treatment fields and also in identifying those patients who have distant metastatic disease and are candidates for palliative chemotherapy rather than curative-intent chemoradiation therapy.

LYMPH NODE DISSECTION

As a part of primary cancer staging, surgical evaluation of retroperitoneal pelvic and paraaortic lymph nodes offers accurate metastasis detection that is superior to radiologic imaging (Goff, 1999). This information is now incorporated into 2018 FIGO staging system. As a result, lymph node dissection may modify a patient's primary treatment strategy based on the level of nodal disease. For example, radiation fields may be altered to ensure that patients with negative paraaortic lymph nodes are not overtreated with extended-field radiation and that patients with positive paraaortic lymph nodes are not undertreated. Potential candidates include patients with positive or suspected positive pelvic nodes undergoing chemoradiation treatment. Supporting studies show that if positive pelvic/paraaortic nodes are identified, patients may receive a significant survival benefit from extended chemotherapy and/or extended field radiation therapy (Hacker, 1995; Holcomb, 1999; Leblanc, 2007).

In addition, tumor-laden nodes may be debulked. Several studies report similar disease-free survival rates for patients whose macroscopic nodal disease is resected compared with women with microscopic nodal disease (Cosin, 1998; Downey, 1989; Hacker, 1995). That said, there is virtually no long-term survival for patients with unresectable bulky paraaortic lymph nodes.

During lymphadenectomy, most experts recommend lymph node dissection in the common iliac and paraaortic region and resection of macroscopic lymph nodes (Querleu, 2000). Traditional laparotomy and minimally invasive surgery (MIS) approaches have been compared. Although diagnostically equivalent, laparoscopic approaches offer postoperative MIS advantages. In addition, laparoscopic lymph node dissection has been associated with significantly less radiation morbidity than that with radiation following laparotomic approaches (Vasilev, 1995).

Despite these suggested benefits, some experts argue that the benefits of surgical staging, if any, are minimal. These studies estimate only a 4- to 6-percent survival benefit after aggressive surgical debulking of retroperitoneal lymph nodes (Kupets, 2002; Petereit, 1998).

PROGNOSIS

The significance of tumor burden on survival rates is well demonstrated, whether measured by FIGO stage, centimeter size, or surgical staging (Stehman, 1991). Of these definers, FIGO stage is the most significant prognostic factor (Table 30-5). Lymph node involvement is an important prognostic feature, and modified prognosis before it was formally incorporated into the staging system. For example, in early-stage cervical cancer (stages I through IIA), nodal metastases are an independent predictor of survival (Delgado, 1990; Tinga, 1990). One GOG study demonstrated a 3-year survival rate of 86 percent for women with early-stage cervical cancer and negative pelvic lymph nodes, compared with a 3-year survival rate of 74 percent in patients who had one or more positive lymph nodes (Delgado, 1990).

In addition, the number of nodal metastases is predictive. Studies demonstrate significantly higher 5-year survival rates in those with one positive lymph node compared with rates in women with multiple involved nodes (Tinga, 1990). In advanced-stage (stage IIB through IV) cervical cancer, lymph node metastases also worsen prognosis. In general, microscopic nodal involvement has a better prognosis than macroscopic nodal disease (Cosin, 1998; Hacker, 1995).

TABLE 30-5. Cervical Cancer Survival Rates According to Stage

Stage	5-Year Survival
IA	100%
IB	88%
IIA	68%
IIB	44%
III	18–39%
IVA	18–34%

Compiled from Grigsby, 1991; Komaki, 1995; Webb, 1980.

EARLY-STAGE PRIMARY DISEASE TREATMENT

Stage IA

The term *microinvasive cervical cancer* identifies this group of small tumors. By definition, these tumors are not visible to the naked eye. Specifically, criteria for stage IA tumors limit invasion depth to <5 mm (see Table 30-4). The microscopic lateral extent of the tumor is no longer factored (Bhatla, 2019). Stage IA tumors are further divided into IA1 and IA2. This subdivision reflects the greater risk for lymph node involvement with increasing depth of invasion. That said, microinvasive cervical cancer carries a minor risk of lymph node involvement and excellent prognosis following treatment.

Stage IA1

These microinvasive tumors invade <3 mm and are associated with the lowest risk for lymph node metastasis. Squamous cervical cancers with stromal invasion <1 mm have a 1-percent risk of nodal metastasis, and those with 1 to 3 mm of stromal invasion carry a 1.5-percent risk. Of 4098 women studied with this tumor stage, <1 percent died of disease following surgery (Ostor, 1995). Because of the low risk of spread into the parametrial or uterosacral nodes, these lesions may be effectively treated with cervical conization alone (Table 30-6) (Keighley, 1968; Kolstad, 1989; Morris, 1993; Ostor, 1994). However, a total extrafascial hysterectomy (type I hysterectomy) is preferred for women who have completed childbearing. Hysterectomy types are described in Table 30-7.

In stage IA1 microinvasive cancers, the presence of LVSI increases the risk of lymph node metastasis and cancer recurrence to approximately 5 percent. Accordingly, at our institution, these cases are traditionally managed with modified radical hysterectomy (type II hysterectomy) and pelvic lymphadenectomy. Radical trachelectomy with pelvic lymph node dissection can be considered in those patients desiring fertility preservation (Olawaiye, 2009).

Adenocarcinomas are typically diagnosed at a more advanced stage than squamous cell cervical cancers. Thus, microinvasive adenocarcinomas present a unique management dilemma, due to sparse data regarding this tumor stage. However, based on evaluation of Surveillance Epidemiology and End Result (SEER) data provided by the National Cancer Institute, the incidence of lymph node involvement is similar to that with squamous cancers (Smith, 2002; Spoozak, 2012). Of microinvasive cervical adenocarcinomas, 59 cases managed with uterine preservation and conization have been reported in the literature (Baalbergen, 2011; Bisseling, 2007; Ceballos, 2006; McHale, 2001; Reynolds, 2010; Schorge, 2000; Yahata, 2010). Of these cases, following conization, no recurrences were identified during surveillance in women without LVSI. According to SEER data, the 5-year overall survival rate for women with stage IA1 adenocarcinoma treated with conization is 98 percent (Spoozak, 2012).

TABLE 30-6. General Treatment for Primary Invasive Cervical Carcinoma[a]

Cancer Stage	Treatment
IA1[c]	Simple hysterectomy preferred if childbearing completed ***or*** Cervical conization
IA1[c] (with LVSI)	Modified radical hysterectomy + PLND (consider SNLB) ***or*** Radical trachelectomy + PLND (consider SNLB) for selected patients desiring fertility
IA2[b,c]	Radical hysterectomy + PLND (consider SNLB) ***or*** Radical trachelectomy + PLND (consider SNLB) for selected patients desiring fertility
IB1[b] to IIA1	Radical hysterectomy + PLND (consider SNLB if tumor <2 cm) ***or*** Radical trachelectomy + PLND for selected patients desiring fertility ***or*** Chemoradiation
Bulky IB3 to IIA2	Chemoradiation
IIB to IVA	Chemoradiation ***or*** Rarely pelvic exenteration[d]
IVB	Palliative chemotherapy ***and/or*** Palliative radiotherapy ***OR*** Supportive care (hospice)

[a]For individual patients, recommendations for treatment can vary, depending on the clinical circumstances.
[b]Some institutions perform modified (type II) radical hysterectomy + PLND for stage IA2 lesions and smaller stage IB tumors.
[c]Intracavitary brachytherapy may be selected for nonsurgical candidates.
[d]A patient with stage IVA lesion with a fistula may be a candidate for a pelvic exenteration.
PLND = pelvic lymphadenectomy; SNLB = sentinel lymph node biopsy.

Stage IA2

These microinvasive cervical lesions have stromal invasion that measures ≥3 mm to <5 mm. These cancers have a 7-percent risk of lymph node metastasis and carry a >4-percent risk of disease recurrence. In this group of women, the safety of conservative therapy is yet to be proven. Thus, for this degree of invasion, radical (or modified radical) hysterectomy and pelvic lymphadenectomy is recommended.

For fertility preservation, stage IA2 squamous cervical lesions may be treated with radical trachelectomy and lymphadenectomy. A nonabsorbable cerclage may be placed concurrently with radical trachelectomy to improve cervical competence during pregnancy. These procedures have high cure rates, and successful pregnancies have been reported. If women are carefully selected for age <45 years, smaller tumor size (<2 cm), and negative nodal involvement, then reported recurrence rates are similar to those of radical hysterectomy (Burnett, 2003; Covens, 1999a,b; Gien, 2010; Olawaiye, 2009). Some experts will offer radical trachelectomy to patients with tumors up to 4 cm (stage IB2). However, prior to surgery, approximately one third of patients with this tumor stage will instead be found to need radical hysterectomy or adjuvant chemoradiation due to intermediate- or high-risk features (Abu-Rustum, 2008; Gien, 2010). Preoperative MR imaging to evaluate the parametria and/or CT scan to evaluate extracervical disease is recommended in these cases. If tumor has extended proximally past the internal cervical os, trachelectomy is contraindicated. Although this technique is promising, it carries a learning curve, and further studies to validate its efficacy are needed.

In addition to stage IA1 tumors, some centers are evaluating the safety of conization or extrafascial hysterectomy for a broader group of women with early-stage cervical cancer, since parametrial involvement in microinvasive cervical cancer is rare (Hou, 2011). One study, which included 51 women with stage IA1 to stage IB1 cervical cancer, demonstrated no recurrences at a median surveillance of 21 months for women treated with conization or extrafascial hysterectomy and no nodal dissection (Bouchard-Fortier, 2014). Two women received adjuvant chemoradiation based on specimen histologic analysis results. In addition, SEER data that included 3987 women with IA1 or 1A2 disease showed similar survival rates for women with adenocarcinoma treated with conization compared with hysterectomy

TABLE 30-7. Tissues Resected During Simple and Extended Hysterectomy

Procedure[b]	Type[c]	Involved Tissues[a]			
		Parametria & Paracolpos	Uterine Vessels	Uterosacral Ligament	Vagina
Simple hysterectomy	I	Preserve	Ligate at uterine isthmus	Transect at uterine insertion	Preserve
Modified radical hysterectomy	II	Removed medial to ureter	Ligate at level of ureter	Transect midway between uterus & rectum	Remove 1–2 cm
Radical abdominal hysterectomy	III	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels	Transect near rectum[d]	Remove ≥2 cm
Type	IV[e]	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels; ligate superior vesical artery	Transect near rectum	Remove 3/4ths
Type	V[e,f]	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels; ligate superior vesical artery	Transect near rectum	Remove 3/4ths
Radical vaginal hysterectomy		Removed medial to ureter	Ligate at level of ureter	Partially removed	Remove ≥2 cm
Radical vaginal trachelectomy		Partially removed	Ligate descending cervicovaginal branch	Transect midway between uterus & rectum	Remove 1–2 cm
Radical abdominal trachelectomy		Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels	Transect near rectum	Remove ≥2 cm

[a]Pelvic lymph node dissection accompanies all except simple hysterectomy.
[b]Hysterectomy includes corpus and cervix removal. For all procedures, unaffected ovaries may remain in premenopausal women, but entire adnexa are usually removed in postmenopausal patients.
[c]Rutledge classification of extended hysterectomy (Piver, 1974).
[d]Although Piver, 1974, described resection of the entire uterosacral ligament, this is not done in practice today due to the high incidence of urinary retention. Instead, the uterosacral ligaments are divided near the rectum.
[e]Although described by Piver, 1974, these procedures are currently not used clinically.
[f]With Type V, the bladder and proximal ureter are removed and requires utereroileoneocystostomy.

(extrafacial or radical). However, women with squamous cell carcinoma undergoing hysterectomy had improved survival rates compared with women undergoing conization (Spoozak, 2012).

Alternatively, patients with stage IA1 and IA2 cervical cancer can be treated with intracavitary brachytherapy alone with excellent results (Grigsby, 1991; Hamberger, 1978). Potential candidates for vaginal brachytherapy include women who are elderly or who are not surgical candidates due to comorbid medical disease.

Hysterectomy

Women with FIGO stage IA2 through IIA cervical cancer, that is, those without obvious parametrial involvement, may be selected for radical hysterectomy plus pelvic lymph node dissection and with or without paraaortic lymph node dissection. Surgery is appropriate for those who are physically able to tolerate an aggressive surgical procedure, those who wish to avoid the long-term effects of radiation therapy, and/or those who have contraindications to pelvic radiotherapy. Typical candidates include young women who desire ovarian preservation and retention of a functional, nonirradiated vagina.

Historically, five types of hysterectomy were described by Piver and colleagues (1974). However, hysterectomy techniques used clinically today vary depending on the degree of surrounding tissue that is resected and are categorized as type I, II, or III (see Table 30-7).

Type I hysterectomy is also known as an *extrafascial hysterectomy* or *simple hysterectomy*. It removes the uterus and cervix but does not require excision of the parametrium or paracolpium. It is appropriately selected for benign gynecologic pathology, preinvasive cervical disease, and stage IA1 cervical cancer.

Type II hysterectomy is also known as *modified radical hysterectomy*. With it, the cervix, proximal vagina, and parametrial and paracervical tissues are removed. This hysterectomy is well suited for tumors in patients with stage IA1 cervical cancer who have positive margins following conization and have insufficient cervix to repeat conization. This hysterectomy

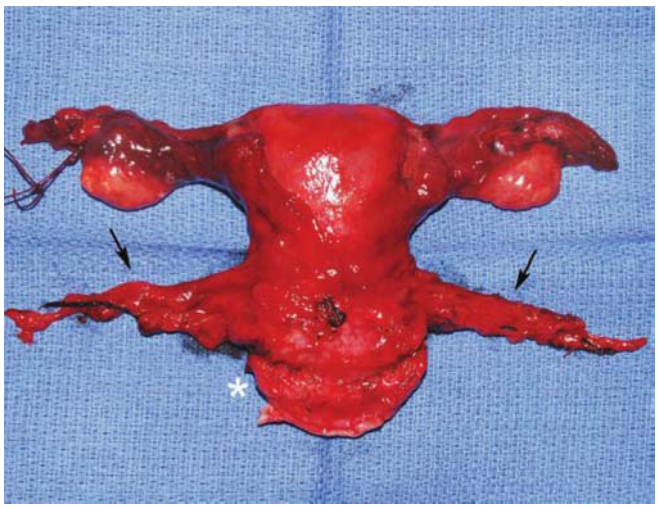

FIGURE 30-11 Gross surgical specimen following radical hysterectomy. The specimen includes the adnexa, uterus, parametria (*arrows*), and segment of proximal vagina (*asterisk*).

is also appropriate for patients with stage IA1 cervical cancer with LVSI. Some institutions perform type II hysterectomies in women with stage IA2 tumors and smaller stage IB tumors with good outcomes (Landoni, 2001).

Type III hysterectomy, also known as *radical hysterectomy*, requires greater resection of the parametria. Its goal is to remove microscopic disease that has extended into the parametrium and paracolpium, and around the uterosacral ligaments. To summarize surgical steps, the uterine arteries are ligated at their origin from the internal iliac arteries near the pelvic sidewall, and all tissue medial to this origin, that is, the parametrium, is resected (Fig. 30-11) (Section 46-1, p. 1160). The ureters are completely dissected from their beds and moved laterally for protection during wide excision of the parametrium and paracolpium. The bladder and rectum are mobilized caudally and off the vagina to permit resection of ≥2 cm of proximal vagina. The uterosacral ligaments are clamped at their midpoint. This procedure is performed for stage IA2, stage 1B2, stage IIA1; for some stage 1B3 lesions; and for patients with relative contraindications to radiation. These contraindications include diabetes, pelvic inflammatory disease, hypertension, collagen disease, inflammatory bowel disease, or adnexal masses.

Previously, the approach for type I, II, and III hysterectomies was abdominal, laparoscopic, robot-assisted, or vaginal. Selection was influenced by patient characteristics and surgeon experience. Advantages of MIS include less blood loss and shorter hospital stay. Intra- and postoperative complications are similar regardless of approach (Ramirez, 2008). However, in 2018, the results of the randomized Laparoscopic Approach to Cervical Cancer (LACC) Trial were published. In this trial, women with FIGO 2009 stage IA1 with LVSI, IA2, or IB1 cervical cancer underwent hysterectomy by a MIS or laparotomy approach. This trial was closed early because women in the MIS group compared with the laparotomy group had worse disease-free rates (86 versus 96.5 percent at 4.5 years) and overall survival rates (93.8 versus 99 percent at 3 years), respectively (Ramirez, 2018). Similarly, in a cohort study of 2461 women with stage IA2 or IB1 cervical cancer who underwent radical hysterectomy and a median follow-up of 45 months, women who underwent MIS had a higher mortality rate (Melamed, 2018). Subgroup analysis found a higher risk for tumor size >2 cm, but the study was underpowered to detect a difference in tumors <2 cm. If MIS is considered, women should be well counseled regarding all potential risks and benefits.

Radical Trachelectomy

This surgical option can preserve fertility in selected young women with cervical cancer, and the cancer stages appropriate for radical trachelectomy mirror those for radical hysterectomy. Compared with radical hysterectomy, radical trachelectomy is less often performed.

Radical trachelectomy was originally completed vaginally, as described by Dargent (2000), but an abdominal approach is now used more commonly (Abu-Rustum, 2006). The abdominal approach allows for a larger resection of the parametria and is suitable for patients with larger tumors (>2 cm). With radical trachelectomy, steps of radical hysterectomy proceed and thus the uterine vessels are ligated, the parametria is resected, ureterolysis is completed, the bladder and rectum are mobilized, and the upper vagina is resected. To remove the cervix, the uterus is incised at or just below the level of the internal os, with the goal to leave 5 mm of endocervix still attached to the uterus. At this remaining endocervical margin, a thin tissue sample is sharply excised, termed a *shave margin*, and sent for frozen section. If cancer is absent in this specimen, reconstruction may proceed. For this, a cerclage using permanent suture is placed, and the knot is tied posteriorly. The uterus is then stitched to the vagina using absorbable sutures. From each side, the corpus ultimately retains blood supply through the uterine branch of the ovarian artery.

Following radical trachelectomy, women continue to menstruate, and conception can occur naturally. However, cervical stenosis may develop, and thus intrauterine insemination or in vitro fertilization is often needed. Pregnancies are frequently complicated by second-trimester loss and higher rates of preterm birth (Plante, 2005; Shepherd, 2008). In one review of 485 women for whom a radical abdominal trachelectomy was planned, 47 cases (10 percent) were converted to radical hysterectomy. Another 25 women required adjuvant therapy based on final pathologic specimen findings. Thus, 413 women (85 percent) retained fertility. In this fertile cohort, there were 75 pregnancies, 18 miscarriages, and 47 deliveries (19 term, 12 preterm, 16 not stated), and 10 women were pregnant at the time of publication (Pareja, 2013). Cesarean delivery with a classical incision is recommended.

Stage IB to IIA

Stage IB lesions are defined as those extending past the limits of microinvasion yet still confined to the cervix. This stage is now subcategorized as IB1 if tumors measure <2 cm or as IB2 if they measure ≥2 cm but <4 cm. Last, IB3 describes lesions measuring ≥4 cm (Fig. 30-12).

Stage II cancers extend outside the cervix. They may invade the upper vagina and the parametria but do not reach the pelvic

FIGURE 30-12 Computed tomography (CT) scan of stage IB3 cervical cancer (*arrow*).

sidewalls. Stage IIA tumors have no parametrial involvement but can extend vaginally as far as the proximal two thirds of the vagina. Stage IIA is further subdivided into stage IIA1 for tumor size <4 cm and IIA2 for tumor size ≥4 cm. Stage IIB cancer may invade the vagina to a similar extent and also invade the parametria.

Treatment

Stage IB to IIA cancers do not extend into the parametria and thus can be managed with either surgery or chemoradiation. In a prospective study of primary therapy, 393 women were randomly assigned to undergo radical hysterectomy and pelvic lymphadenectomy or receive primary radiation therapy. Five-year overall survival and disease-free survival rates were statistically equivalent (83 percent and 74 percent, respectively). Patients who underwent radical surgery followed by radiation had the worst morbidity (Landoni, 1997).

Because chemoradiation and surgery are both viable options, the optimum treatment for each woman ideally assesses clinical factors such as menopausal status, age, concurrent medical illness, tumor histology, and cervical diameter. For stage IB1 and IIA1 cervical cancers, it is left to the physician's discretion and patient preference as to which treatment modality is preferred. Our general approach to patients with bulky stage IB3 or stage II cervical cancers, that is, those measuring >4 cm, is to manage them primarily with chemoradiation, in a similar fashion to advanced-stage cervical cancers.

In general, radical hysterectomy for stage IB through IIA tumors is usually selected for premenopausal women who wish to preserve ovarian function and for women who have concerns about altered sexual functioning following radiotherapy. Age and weight are not contraindications to surgery. However, in general, older women may have longer hospital stays, and heavier women can have longer operative time, greater blood loss, and higher rates of wound complications. Surgery is contraindicated in patients with severe cardiac or pulmonary disease.

In those electing surgery, oophorectomy may be deferred in younger women. One GOG study evaluated tumor spread to the ovary in those with IB tumors electing radical hysterectomy without adnexectomy. Ovarian metastases were identified in only 0.5 percent of 770 women with stage IB squamous cell cancers and in 2 percent of those with adenocarcinomas (Sutton, 1992). For those electing ovarian preservation, ovarian transposition, accomplished by oophoropexy of the ovary into the upper abdomen, can be performed during radical hysterectomy. This repositioning helps preserve ovarian function, in case postoperative pelvic radiation is indicated. In addition, to reduce complications from radiotherapy that might be needed following radical hysterectomy, a surgeon may perform an omental J-flap. Namely, after surgery, the small bowel may become fixed in the pelvis by adhesions, which renders it vulnerable to radiation damage. The omental J-flap can fill the pelvis to reduce this adhesion risk and is described in Section 46-8 (p. 1186).

Systematic lymphadenectomy can lead to complications such as lymphocyst and lymphedema. Therefore, in women with cervical cancer, sentinel lymph node biopsy is an attractive option to assess lymphatic spread yet avoid extensive nodal resection. As a review, the sentinel node is the first node(s) receiving lymphatic drainage from a given tumor. To find this node, either a blue-colored vital dye or a technetium radioactive tracer or both are separately injected preoperatively into the cervix. At surgery, the sentinel node is stained blue and emits radioactivity discernible by Geiger counter. From a metaanalysis including 67 studies, the pooled sentinel node detection rate was 89 percent and sensitivity was 90 percent. Both were highest in women injected with both radiotracer and dye. Smaller tumor size (<2 cm) and early-stage disease were associated with the highest sensitivity and detection rate (Kadkhodayan, 2015). Sentinel lymph node biopsy can be considered for women with tumors <2 cm and is now included in the National Comprehensive Cancer Guidelines (Altgassen, 2008; Koh, 2019; Salvo, 2017).

Weighing Surgical and Radiotherapy Complications

Complications for early-stage cervical cancer radical surgery include ureteral stricture, vaginal fistulas, bladder dysfunction, constipation, wound breakdown, lymphocyst, and lymphedema. The risk of venous thromboembolism warrants chemoprophylaxis and/or sequential compression devices as outlined in Table 39-10 (p. 834). If radiotherapy is added as an adjuvant to surgery, the risk of many of these is increased.

On the other hand, radiation therapy also carries long-term complications described in Chapter 28 (p. 615). Of these, altered sexual function secondary to a shortened vagina, dyspareunia, psychologic factors, and vaginal stenosis are common. Late urinary and bowel complications such as fistula formation, enteritis, proctitis, and bowel obstruction also may develop following radiotherapy.

Positive Pelvic Lymph Nodes

Approximately 15 percent of patients with clinical stage I through IIA cervical cancers will have positive pelvic nodes. Risk factors for lymph node involvement include those listed in Table 30-8. Of those with involved nodes, 50 percent will have grossly positive pelvic nodes intraoperatively. In most cases involving grossly positive nodes, radical hysterectomy is

TABLE 30-8. Percentage of Cases with Positive Pelvic Lymph Nodes by Pathologic Factors[a]

Factor	(%)	*p* value

abandoned. After recovering from surgery, whole-pelvic radiation and brachytherapy with concomitant chemotherapy is administered. The 50 percent of patients with involved nodes not grossly identified intraoperatively are considered to be at high risk of recurrence following their radical hysterectomy. As described subsequently, these women require postoperative adjuvant chemoradiation therapy.

Recurrence Risk

For women who have completed radical surgery for early-stage cervical cancer, the GOG has defined risk factors to help identify women for tumor recurrence. *Intermediate risk* describes those who on average would have a 30-percent risk of cancer recurrence within 3 years. Factors included in this model are depth of tumor invasion, clinical tumor diameter, and LVSI.

To determine appropriate treatment, patients with these intermediate-risk factors have been studied. In one trial, women were randomly assigned to receive pelvic radiation therapy following radical hysterectomy or to undergo radical hysterectomy and observation. A nearly 50-percent reduced risk of recurrence was found in those who received postoperative adjuvant radiation therapy (Sedlis, 1999). However, this adjuvant radiation did not prolong overall survival. Notably, these patients did not receive chemotherapy coupled with their radiation. In our practice, these intermediate-risk patients are counseled regarding their recurrence risk and offered the option of adjuvant chemoradiation therapy. A GOG clinical trial (GOG #263) that is assessing chemoradiation in this patient population is ongoing.

A *high-risk* category for early-stage cervical cancer patients who underwent radical surgery also has been described. High risk is defined as a 50- to 70-percent risk of recurrence within 5 years. These women have positive lymph nodes, positive surgical margins, or microscopically positive parametria (Peters, 2000). This group is routinely offered adjuvant radiation therapy. Moreover, the GOG demonstrated that the addition of concurrent chemotherapy significantly prolongs disease-free and overall survival rates in this group of women with high-risk early-stage cancer (Peters, 2000).

Adjuvant Hysterectomy Following Primary Radiation

Treating bulky stage I (previous stage IB2, now IB3) cervical cancers with adjuvant hysterectomy after radiation therapy has been evaluated. Adjuvant hysterectomy reduces locoregional relapse but does not contribute to an overall improvement in survival rates. However, initial lesion size may affect efficacy. In one study, those with tumors measuring <7 cm who underwent postradiation hysterectomy survived longer than did women with equivalent tumors in the radiation-only regimen group. In contrast, those with lesions ≥7 cm who underwent postradiation hysterectomy fared worse than their counterparts receiving only radiotherapy (Keys, 2003).

Early-Stage Cervical Adenocarcinoma

These cancers may be more radioresistant than squamous cell cervical carcinomas. Although some prefer radical hysterectomy to radiotherapy, studies suggest equivalent survival rates with either (Eifel, 1991, 1995; Hopkins, 1988; Nakano, 1995). However, larger lesions may not regress if managed by radiation alone (Leveque, 1998; Silver, 1998). The centers of bulky tumors may be less radiosensitive due to relative cellular hypoxia. This effect underscores the advantages of radical hysterectomy for women with stage I cervical adenocarcinoma.

ADVANCED-STAGE PRIMARY DISEASE TREATMENT

Stages IIB to IVA

Advanced-stage cervical cancers extend past the confines of the cervix and often involve adjacent organs and retroperitoneal lymph nodes. Untreated, these tumors progress rapidly.

Management is individualized, yet most advanced-stage tumors have a poor prognosis. Five-year survival rates are <50 percent.

Radiation Therapy

This modality forms the cornerstone of advanced-stage cervical cancer management. Both external beam pelvic radiation and brachytherapy are typically delivered (Chap. 28, p. 611). Of these, external beam radiation usually precedes intracavitary radiation, which is one form of brachytherapy. External beam radiation is commonly administered in 25 fractions during 5 weeks (40 to 50 Gy). During evaluation, if paraaortic nodal metastases are found, extended field radiation can be added to treat these affected lymph nodes.

During brachytherapy, bowel and bladder are moved away from the intracavitary source using vaginal packing during tandem insertion to limit radiation to these organs. Treatment is often prescribed to point A, that is, a point 2 cm lateral and 2 cm superior to the external cervical os, and to point B, which is a point 3 cm lateral to point A. Side effects during and following radiation therapy are common, and these are discussed in Chapter 28 (p. 615).

Chemoradiation

Current evidence indicates that chemotherapy given concurrently with radiation therapy significantly improves overall and disease-free survival rates in women with cervical cancer. Chemoradiation is also associated with superior survival rates compared with pelvic and extended field paraaortic region irradiation alone (Morris, 1999).

After five trials demonstrated improved survival rates, it is now recommended that cisplatin-based chemotherapy should be considered in women undergoing radiation for cervical cancer (Keys, 1999; Morris, 1999; Peters, 2000; Rose, 1999; Whitney, 1999). The characteristics of this agent are described in Chapter 27 (p. 598), and Figure 30-13 describes its tumoricidal action. Nonplatinum regimens also have activity but have not been directly compared with cisplatin-containing regimens (Vale, 2008). At our institution, cisplatin is given weekly for 5 weeks. It is administered concurrently with external beam radiation and with brachytherapy. Unfortunately, the recurrence risk remains as high as 40 percent after chemoradiation given for curative intent (Chemoradiotherapy for Cervical Cancer Meta-Analysis Collaboration, 2008). Therefore, a large international randomized Phase III trial is currently evaluating whether the addition of adjuvant chemotherapy after completion of chemoradiation improves overall survival rates for women with stage IB1 with positive nodes and for those with stage IB2 through IVA disease.

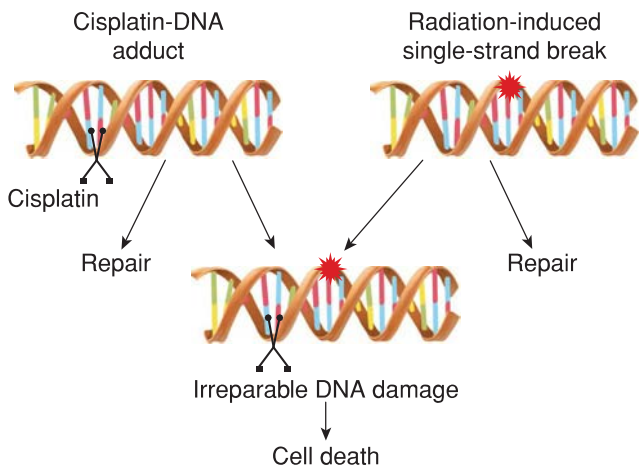

FIGURE 30-13 Cisplatin can bind covalently to DNA bases. Radiation therapy may create single-strand breaks. If occurring alone, each damaging event is likely to be repaired. However, if both occur in close proximity, irreparable damage can lead to cell death.

Pelvic Exenteration for Primary Disease

This ultraradical surgery encompasses removal of the bladder, rectum, uterus, fallopian tubes and ovaries (if present), vagina, and surrounding tissues (Section 46-5, p. 1180). Primary exenteration may be considered for women with stage IVA cancer, that is, with direct tumor invasion into bladder and/or bowel but without distant spread. Exenteration is rarely performed for this indication, yet for suitable candidates, the survival rate can reach 30 percent (Million, 1972; Upadhyay, 1988).

Stage IVB

Patients with stage IVB disease have a poor prognosis and are treated with a goal of palliation. Pelvic radiation is administered to control vaginal bleeding and pain. Systemic chemotherapy is offered to palliate symptoms and prolong overall survival. The chemotherapy regimens used in this group of women are similar to those used in the setting of recurrent cancer (p. 671).

SURVEILLANCE

Following Radiotherapy

Women who receive radiotherapy are closely monitored to assess their response. Tumors may be expected to regress for up to 3 months after therapy. Pelvic examination and/or radiologic scanning should document progressive shrinkage of the cervical mass. The rectovaginal examination is used to detect nodularity in the ligaments and parametria. If disease progresses locally after this interval, prognosis is poor. Pelvic exenteration may sometimes be indicated for this clinical setting.

In general, patients are seen at 3-month intervals for 2 years, then every 6 months until 5 years have passed from treatment, and then annually. At each visit, in addition to pelvic examination, a thorough manual nodal survey includes neck, supraclavicular, axillary, and inguinal lymph nodes. A cervical or vaginal cuff Pap test also is collected annually for 20 years after treatment completion. Findings of HSIL lesions with screening should prompt colposcopic evaluation and biopsy of suspicious lesions. If recurrent cancer is diagnosed from these biopsies, then CT or PET/CT imaging is performed.

Once radiotherapy is completed, patients are encouraged to use a vaginal dilator or have vaginal intercourse three times per week. This helps keep the vagina patent, aids pelvic examination and Pap tests in the future, and ensures that the patient can remain sexually active if desired. Otherwise, radiation may

result in vaginal fibrosis, which can create a shortened, nonfunctional vagina. The use of a water-based lubricant is recommended.

Following Surgery

After a radical hysterectomy, 80 percent of recurrences are detected within the subsequent 2 years. During patient surveillance, an abnormal pelvic mass or abnormal pelvic examination finding typically prompts CT scanning of the abdomen and pelvis. Clinical findings include cervical or vaginal lesion, rectovaginal nodularity, pain radiating down the posterior thigh, or new-onset lower extremity edema. Pelvic recurrences after radical hysterectomy, if diagnosed early, can be treated with radiation therapy. The same schedule of visits and Pap tests as outlined above for surveillance following radiotherapy is then recommended.

Hormone Therapy

Cervical cancer is not estrogen-dependent and thus hormone therapy is not contraindicated to treat menopausal symptoms (Chap. 22, p. 480). Moreover, hormone therapy is strongly considered for any premenopausal patient undergoing radiation treatment for cervical cancer until the average age of menopause. This is because radiation doses given for cervical cancer lead to menopause. Ovaries previously transposed out of the pelvic radiation field may be exceptions. Either systemic or vaginal forms of estrogen are suitable. Estrogen alone is used if the uterus has been surgically removed, whereas combination hormonal therapy is given if the uterus remains.

SECONDARY DISEASE

This is defined as either persistent or recurrent cancer. *Persistent disease* is cervical cancer that has not completely regressed within 3 months of finishing radiotherapy. *Recurrent disease* is defined as a new lesion after primary therapy completion and initial regression.

Treatment of persistent or recurrent disease depends on its location and extent. The intent in these cases is usually palliative. However, in certain instances, a woman may qualify for pelvic radiation if she previously had not received this treatment. Alternatively, a woman may be a candidate for curative-intent surgery. Metastatic cervical cancer is not curable. In this setting, the goal of chemotherapy is to maximize existing patient quality of life and prolong survival.

Pelvic Exenteration for Secondary Disease

When curative-intent surgery is contemplated, local disease should be biopsy proven. Clinically, a patient may be considered for pelvic exenteration if the triad of lower extremity edema, back pain, and hydronephrosis are absent. If present, these suggest disease extension to the pelvic sidewalls, which would contraindicate surgery. In addition, regional and distant metastasis should be excluded by both physical examination and radiologic imaging, which typically is a PET/CT scan.

Pelvic exenteration begins with exploratory laparotomy, biopsies of suspicious lesions, and paraaortic lymph node evaluation. Exenteration is completed only if no disease is found in frozen section specimens sampled at the beginning of surgery. A complete surgical description of this procedure is found in Section 46-5 (p. 1180).

Alternatively, in highly selected patients, radical hysterectomy may be considered as an alternative to pelvic exenteration (Coleman, 1994). In these circumstances, women should have small cervical recurrences measuring <2 cm and have disease-free pelvic lymph nodes both prior to and during surgery.

With either operation, intraoperative and postoperative complications can be significant. Reported 5-year survival rates approximate 50 percent. Most recurrences occur in the first 2 years postoperatively (Berek, 2005; Goldberg, 2006).

Radiotherapy or Chemotherapy for Secondary Disease

Patients with central or limited peripheral recurrences who are radiotherapy naïve are candidates for curative-intent chemoradiation treatment. In these groups, survival rates of 30 to 70 percent have been reported (Ijaz, 1998; Ito, 1997; Lanciano, 1996; Potter, 1990).

Antineoplastic drugs are used to palliate both disease and symptoms of advanced, persistent, or recurrent cervical cancer (Table 30-9). Cisplatin is considered the single most active cytotoxic agent in this setting (Thigpen, 1995). Overall, response duration to cisplatin is 4 to 6 months, and survival in such women only approximates 7 months (Vermorken, 1993). A four-arm prospective randomized study demonstrated that the combinations of cisplatin with topotecan, vinorelbine, or gemcitabine are not superior to the combination of cisplatin and paclitaxel (Monk, 2009). More recently, a randomized study evaluated adding bevacizumab, which is a monoclonal antibody targeting vascular endothelial growth factor (VEGF), to combination chemotherapy. This addition increased the median overall survival length by 3.7 months (see Table 30-9) (Tewari, 2014).

Pembrolizumab (Keytruda) is an immune checkpoint inhibitor against programmed cell death 1 (PD-1), described in Chapter 27 (p. 601). This was approved in 2018 for women with recurrent or persistent cervical cancer with a combined positive score (CPS) ≥1 who have cancer progression despite systemic chemotherapy (Chung, 2019). The CPS is the number of positive PD-L1 cells (tumor cells, lymphocytes, and macrophages), divided by the total number of viable tumor cells and then multiplied by 100.

PALLIATIVE CARE

Palliative chemotherapy is administered only if this treatment does not significantly lower patient quality of life and is balanced against the benefits of supportive care. Women with persistent nausea and vomiting from tumor-associated ileus may benefit from a gastrostomy tube. Bowel obstruction can be managed surgically, provided a patient is an appropriate surgical

TABLE 30-9. Combination Chemotherapy Regimens and Response Rates of Cervical Cancer

Study	Chemotherapy Agents	Response Rates (%)	Progression-Free Survival (months)	Overall Survival (months)

candidate. Percutaneous nephrostomy tubes may be placed for urinary fistulas or urinary tract obstruction.

Pain management forms the basis of palliation. Cervical cancer patients can experience significant pain, and this is assessed at each visit. Many will require narcotics (Table 42-3, p. 910). If a patient has been using opioids and is hospitalized for inadequate pain control, patient-controlled analgesia is considered. The total dose that controls the pain in a 24-hour period is determined. This dose can then be converted an equivalent dose of long-acting opioids. To allow for incomplete cross-tolerance between narcotics, the dose should be decreased by 25 to 50 percent. A supplemental short-acting opioid can be available for breakthrough pain and is typically prescribed at a dose that is 10 to 20 percent of the long-acting total daily dose and given at appropriate intervals.

Narcotics can constipate, and patients using these are given a bowel regimen. This can be individualized, and suitable agents are listed in Table 25-5 (p. 566). In particular, a combination of stool softeners (docusate sodium) plus laxative (senna) plus polyethylene glycol is often effective.

We recommend discussion of medical directives if a patient has adequate mental capability. Often, such discussion is conducted over time, giving a woman an opportunity to understand the severity and progression of her disease. Home hospice is an invaluable part of terminal care for most of these women, who require intensive pain management and considerable assistance with daily living activities.

MANAGEMENT DURING PREGNANCY

Survival rates between pregnant and nonpregnant women with cervical cancer do not differ when matched by age, stage, and year of diagnosis. Overall survival rates are slightly better for cervical cancer in pregnancy, because a greater proportion of patients have stage I disease.

Diagnosis

A Pap test is recommended for all pregnant patients older than 21 at the initial prenatal visit. Additionally, clinically suspicious lesions are directly biopsied. If Pap test results reveal HSIL, adenocarcinoma in situ (AIS), or suspected malignancy, colposcopy is performed and biopsies are obtained. However, endocervical curettage is excluded to prevent amnionic sac rupture.

If Pap testing indicates malignant cells and colposcopy-directed biopsy fails to confirm malignancy, diagnostic conization may be necessary. Many experts recommend delaying conization until the second trimester due to concern for pregnancy loss. However, median blood loss during excisional procedures increases with gestational age, especially in the third trimester. In pregnant patients, the loop electrosurgical excision procedure (LEEP) does not appear to offer an advantage compared with cold-knife conization. Moreover, one study found a surgical complication rate of 25 percent with LEEP in pregnancy, and 47 percent of the women had persistent or recurrent disease (Robinson, 1997).

Stages I and II Cancer in Pregnancy

Women with microinvasive squamous cell cervical carcinoma found during conization that measures <3 mm and contains no LVSI (stage IA1) may deliver vaginally and be reevaluated 6 weeks postpartum. Moreover, for those with stage IA or IB disease, studies find no greater maternal risk if treatment is intentionally delayed to optimize fetal maturity regardless of the trimester in which the cancer was diagnosed. Given the outcomes, a planned treatment delay is generally acceptable for women who are 20 or more weeks' gestational age at diagnosis with stage I disease and who desire to continue their pregnancy.

However, a patient may be able to delay from earlier gestational ages if she wishes. For women who wish to continue pregnancy, pelvic lymph node dissection can be performed in pregnancy in the first and second trimester using MIS

(Vercellino, 2014). Women with positive nodes may elect to be treated with definitive treatment, rather than delay. For definitive treatment with early-stage disease, a radical hysterectomy with the fetus in situ and lymphadenectomy can be performed. Instead, a gravida may opt for neoadjuvant chemotherapy during pregnancy or for early delivery. For patients with stage IA2 through IIA1, a cesarean section via a classical uterine incision may be performed at term, followed immediately by radical hysterectomy and lymph node dissection. Notably, a classical cesarean incision minimizes the risk of cutting through tumor in the lower uterine segment, which can cause serious blood loss and result in tumor spread.

Advanced Cervical Cancer in Pregnancy

Women with advanced cervical cancer diagnosed prior to fetal viability are offered primary chemoradiation. Spontaneous abortion of the fetus tends to follow whole-pelvic radiation therapy. For women who decline pregnancy termination, systemic chemotherapy can be administered. Cisplatin with vincristine or paclitaxel can be administered in pregnancy. Rates of congenital anomalies, growth restriction, and preterm delivery are not increased in fetuses of women who receive chemotherapy after the first trimester (Cardonick, 2010). If cancer is diagnosed after fetal viability is reached and a delay until fetal pulmonary maturity is elected, then a classical cesarean delivery is performed. Chemoradiation is administered after uterine involution. For patients with advanced disease and treatment delay, pregnancy may impair prognosis. A woman who elects to delay treatment, to provide quantifiable benefit to her fetus, will need to accept an undefined risk of disease progression.

Cancers of the vulva are uncommon and constitute only 6 percent of all gynecologic malignancies. Most vulvar cancers are diagnosed in older women. Early-stage vulvar cancers are highly curable, and thus biopsy of any abnormal vulvar lesion is imperative to help diagnose this cancer expeditiously.

The Surveillance, Epidemiology, and End Results Program (SEER) provides online survival and incidence trends for cancers in the United States. SEER (2018) data from 2008 to 2014 show vulvar cancers carry a 5-year relative survival rate of 71 percent. Historically, treatment of vulvar cancer resulted in extensive short- and long-term morbidity, with dramatic anatomic and functional deformity. Surgery is now more conservative yet preserves oncologic efficacy. For unresectable, locally advanced disease, chemoradiation may be used either primarily or as an adjunct to surgery to aid tumor control.

RELEVANT ANATOMY

The *external vulva* includes the mons pubis, labia majora and minora, clitoris, vestibule, vestibular bulbs, Bartholin glands, lesser vestibular glands, paraurethral glands, and the urethral and vaginal openings. Lateral margins of the vulva are the labiocrural folds (Fig. 38-26, p. 815). Vulvar cancer may involve any of these external structures and typically arises within the covering squamous epithelium. Importantly, unlike the cervix, the vulva lacks an identifiable transformation zone. However, the Hart line on the vestibule marks the border between the vulvar keratinized squamous epithelium, which lies laterally, and the nonkeratinized squamous mucosa, which lies medially. Vulvar squamous neoplasia arises predominantly along the Hart line.

Deep to the external vulva are the superficial and deep urogenital triangle compartments. The superficial space lies between Colles fascia (superficial perineal fascia) and the perineal membrane (deep perineal fascia) (Fig. 38-26 p. 815). Within this space lie the ischiocavernosus, bulbospongiosus, and transverse perineal muscles and the highly vascular vestibular bulb and clitoral crus. During radical vulvectomy, dissection is carried to the depth of the perineal membrane. As a result, contents of this superficial urogenital triangle compartment that lie beneath the mass are removed during tumor excision.

The lymphatics of the vulva and distal third of the vagina typically drain into the superficial inguinal node group (Fig. 38-31, p. 819). From here, lymph travels through the deep femoral lymphatics and the node of Cloquet to the pelvic nodal groups. Importantly, lymph can also drain directly from the clitoris and upper labia to the deep femoral nodes (Way, 1948). Vulvar lymphatics cross at the mons pubis and the posterior fourchette but do not cross the labiocrural folds (Morley, 1976). Thus, lesions found within 2 cm of the midline may spread to either lymph node. In contrast, lateral lesions rarely send metastases to contralateral nodes. This anatomy point influences the decision for ipsilateral or bilateral node dissection, discussed later.

The superficial inguinal nodes cluster within the femoral triangle formed by the inguinal ligament, sartorius muscle, and adductor longus muscle (Fig. 38-31, p. 819). The deep femoral nodes lie within the borders of the fossa ovalis and just medial to the femoral vein. An *inguinofemoral lymphadenectomy* typically refers to removal of both superficial inguinal and deep femoral lymph nodes (Levenback, 1996).

EPIDEMIOLOGY

In the United States, women have a 1 in 333 chance of developing this cancer at some point. For 2019, approximately 6070 new vulvar cancers and 1280 cancer deaths are predicted (Siegel, 2019). SEER (2018) data from 1975 to 2015 show that rates of vulvar cancer have been rising on average by 0.6 percent every year and that the death rate has been increasing yearly by 1.2 percent.

Of vulvar cancers, approximately 90 percent are squamous cell carcinoma (Fig. 31-1). Malignant melanoma is the second most common, but rare histologic subtypes also may be encountered (Table 31-1).

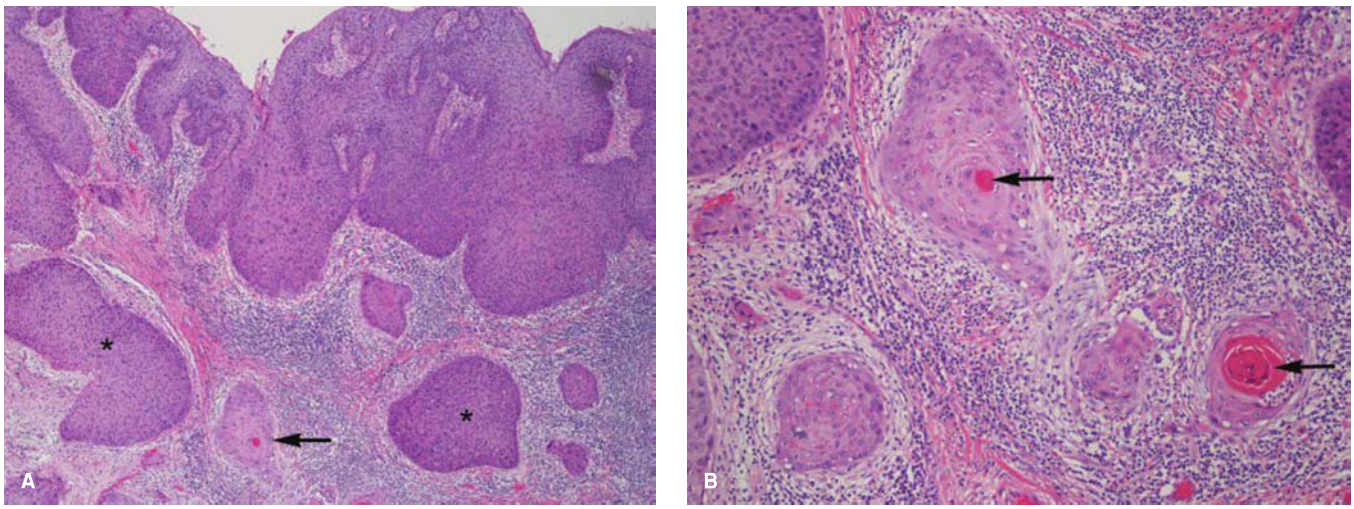

FIGURE 31-1 Vulvar squamous cell carcinoma. **A.** Low-power view. The surface epithelium shows high-grade squamous dysplasia. Nests of invasive squamous cell carcinoma (*arrow*) are present. A brisk chronic inflammatory infiltrate is present as is often the case with invasive squamous cell carcinoma. Portions of the surface epithelium extend deep and are cut tangentially (*asterisks*), giving the false impression of invasive tumor at these sites. **B.** Tumor shows classic diagnostic features of invasive squamous cell carcinoma that include a squamoid appearance, intercellular bridges, and brightly eosinophilic keratin pearls (*arrows*). Nests of invasive tumor are surrounded by chronic inflammation. (Reproduced with permission from Dr. Kelley Carrick.)

RISK FACTORS

The cause of vulvar cancer is unknown, but associated risk factors have been identified. The average age at diagnosis is 65 years, hence *age* is a prominent factor. However, vulvar cancer can develop at any age.

Women who are infected with *human papillomavirus (HPV)* have a greater risk of vulvar cancer. Specifically, 50 to 75 percent of invasive vulvar cancers are associated with high-risk HPV serotypes (Gargano, 2012). Strong correlations also can be seen between high-risk HPV infection and preinvasive lesions of the vulva (Gargano, 2012). HPV becomes a stronger contributor when combined with other cofactors such as smoking or herpes simplex virus (HSV) infection (Madeleine, 1997). Women who have smoked and have a history of HPV genital warts have a 35–fold greater risk for developing vulvar cancer compared with women without these predispositions (Brinton, 1990; Kirschner, 1995).

Vulvar intraepithelial neoplasia (VIN) is considered a preinvasive condition of the vulva and is thoroughly discussed in Chapter 29 (p. 643). VIN is categorized as *usual type VIN* and *differentiated type VIN*. Usual type VIN is associated with high-risk HPV infection and develops usually in young women. In contrast, the differentiated type VIN occurs in postmenopausal women with chronic skin conditions such as lichen sclerosis (Reyes, 2014). Of these two, differentiated type VIN has a significantly stronger association with squamous cell carcinoma compared with usual type VIN (Eva, 2009). Also with VIN, high-grade disease is more closely linked with invasive vulvar cancer. Approximately 4 percent of women with a history of high-grade VIN subsequently develop vulvar cancer (Jones 2005). And, an underlying squamous carcinoma can be found in one fifth of women initially treated for VIN 3 (Modesitt, 1998). Hence, we recommend early definitive treatment for those with high-grade vulvar dysplasia.

Vaccines against HPV have the theoretical potential to lower vulvar neoplasia rates. The nonavalent vaccine (Gardasil 9) is effective against high-risk HPV serotypes 16 and 18 (Huh, 2017). It is hoped that this vaccine will lower future rates of HPV-related invasive cancer (Garland, 2018; Saraiya, 2015).

Chronic immunosuppression can predispose to vulvar cancer. For example, transplant patients have a high incidence. In this group, vulvar cancer develops at a much younger age than in the general population, and more than 50 percent have a prior history of condyloma acuminata (Penn, 2000). With human immunodeficiency virus (HIV) infection, vulvar cancer rates

also are elevated (Elit, 2005; Frisch, 2000). Indeed, HIV-infected patients make up most of the increased high-grade VIN and invasive vulvar carcinoma incidence noted in younger women (Casolati, 2003). A possible explanation is the association of HIV and high-risk HPV serotypes. However, vulvar cancer is not yet considered an acquired immunodeficiency syndrome (AIDS)-defining malignancy. Because of these links with vulvar cancer, we recommend that all immunocompromised women undergo thorough vulvar inspection and, when indicated, vulvoscopy and biopsy.

Lichen sclerosus is a chronic vulvar inflammatory disease and is described in Chapter 4 (p. 94). This condition is related to vulvar cancer development. Keratinocytes affected by lichen sclerosus show a proliferative phenotype and can exhibit markers of neoplastic progression. As such, lichen sclerosus may be a precursor lesion to differentiated type VIN and invasive squamous vulvar cancers (Halonen, 2017).

DIAGNOSIS

Symptoms

Women with VIN and vulvar cancer commonly present with pruritus and a visible lesion (Fig. 31-2). However, pain, bleeding, ulceration, and inguinal mass may be other complaints (Fig. 31-3). Manifestations can persist for weeks or months before diagnosis, as many patients may be embarrassed or may not recognize the significance of their symptoms.

Lesion Evaluation

Lesions may be raised, ulcerated, pigmented, or warty, but in younger women with multifocal disease, a well-defined mass is not always present. Importantly, other clinical entities may present similarly and include VIN, infection, chronic inflammatory disease, and granulomatous disease. Thus, the goal of evaluation is to obtain an accurate and definitive pathologic diagnosis.

FIGURE 31-3 Enlarged inguinal lymph node containing metastatic squamous cell vulvar cancer. (Reproduced with permission from Dr. William Griffith.)

For this, colposcopic examination of the vulva, termed *vulvoscopy,* can direct biopsy site selection. To begin, the vulva is soaked with 3-percent acetic acid for 5 minutes to allow adequate penetration into the keratin layer. This aids identification of acetowhite areas and abnormal vascular patterns, which are characteristics of vulvar neoplasia (Chap. 29, p. 645). The entire vulva and perianal skin are systematically examined. We recommend obtaining multiple biopsies, as illustrated in Figure 4-2 (p. 94), from the most suspicious raised or dyspigmented skin. Specimens removed with a Keyes punch should be approximately 4 mm thick to include the surface epithelial lesion and the underlying stroma. This permits evaluation for invasion and depth of invasion. Concurrent colposcopic examination of the cervix and vagina and careful evaluation of the perianal area are recommended to diagnose any synchronous lesions or associated neoplasm of the lower genital tract.

Cancer Patient Evaluation

Following histologic diagnosis, a patient with vulvar cancer is assessed for the clinical extent of disease and for comorbid conditions. Thus, detailed physical examination includes measurement of the primary tumor and evaluation of cancer extension into other genitourinary compartments, the anal canal, the bony pelvis, and inguinal lymph nodes. At our institution, if a thorough physical examination is not possible because of patient discomfort or disease extent, an examination under anesthesia is performed. This may be coupled with cystourethroscopy, proctosigmoidoscopy, or both if suspicion of tumor invasion into the urethra, bladder, or anal canal is high (Fig. 31-4).

Women with small tumors and clinically negative inguinal nodes require few additional diagnostic studies other than those needed for surgical preparation (Chap. 39, p. 822). Although not a formal part of surgical tumor staging, preoperative imaging should be performed in those with larger tumors or with clinically suspected metastatic disease. In such cases, computed tomography (CT) of the chest, abdomen, and pelvis; positron emission tomography (PET); or magnetic resonance (MR) imaging of the

FIGURE 31-4 Photograph of invasive vulvar cancer involving midline mucosal structures.

abdomen and pelvis provide information regarding disease extent or metastases that may modify preoperative planning.

Staging Systems

The International Federation of Gynecology and Obstetrics (FIGO) advocates staging of patients with vulvar cancer that is based on a tumor, node, metastasis (TNM) classification. Frequently, stage is determined after definitive surgical management. Thus, staging involves: (1) primary tumor evaluation to obtain tumor dimensions and extension and (2) sentinel lymph node biopsy or dissection of superficial and deep inguinofemoral lymph nodes to evaluate tumor spread (Pecorelli, 2009). This system is used to direct treatment and predict prognosis (Van der Steen, 2010). Table 31-2 and Figure 31-5 describe FIGO staging and American Joint Committee on Cancer (AJCC) staging criteria for all vulvar cancer types except melanoma. This cancer's staging is discussed on page 685. The general nuanced differences between FIGO and AJCC systems are described in Chapter 30 (p. 661).

PROGNOSIS

Overall survival rates of women with squamous cell carcinoma of the vulva are relatively good and approximate 65 percent (Razzaghi, 2018). SEER (2018) data from 2008 to 2014 show that a 5-year survival rate of 86 percent can be expected for local disease (stage I and II). As anticipated, 5-year survival rates for higher stages are poorer, and a rate of 54 percent can be expected for regional (stage III and IVA) disease and a rate of 16 percent for stage IVB. Apart from FIGO stage, other important prognostic factors include lymph node metastasis, lesion size, depth of invasion, resected-margin status, and lymphatic vascular space involvement (Table 31-3).

Of these, *lymph node metastasis* is the single most important vulvar cancer predictor, since inguinal node metastasis reduces long-term survival rates by 50 percent (Farias-Eisner, 1994;

TABLE 31-2. Invasive Vulvar Cancer Staging

TNM[a]	Stage[b]	Characteristics
	I	**Tumor confined to the vulva**
T1a	IA	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1.0 mm[c], no nodal metastasis
T1b	IB	Lesions >2 cm in size or with stromal invasion >1.0 mm[c], confined to the vulva or perineum, with negative nodes
T2	**II**	**Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes**
	III	**Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinofemoral lymph nodes**
N1b	IIIA	(i) With 1 lymph node metastasis (≥5 mm), or
N1a		(ii) 1–2 lymph node metastasis(es) (<5 mm)
N2b	IIIB	(i) With 2 or more lymph node metastases (≥5 mm), or
N2a		(ii) 3 or more lymph node metastases (<5 mm)
N2c	IIIC	With positive nodes with extracapsular spread
	IV	**Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures**
T3	IVA	Tumor invades any of the following: (i) upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) fixed or ulcerated inguinofemoral lymph nodes
M1	IVB	Any distant metastasis including pelvic lymph nodes

[a]American Joint Committee on Cancer staging that reflects tumor, nodes, and metastases (TNM).

[c]The *depth of invasion* is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

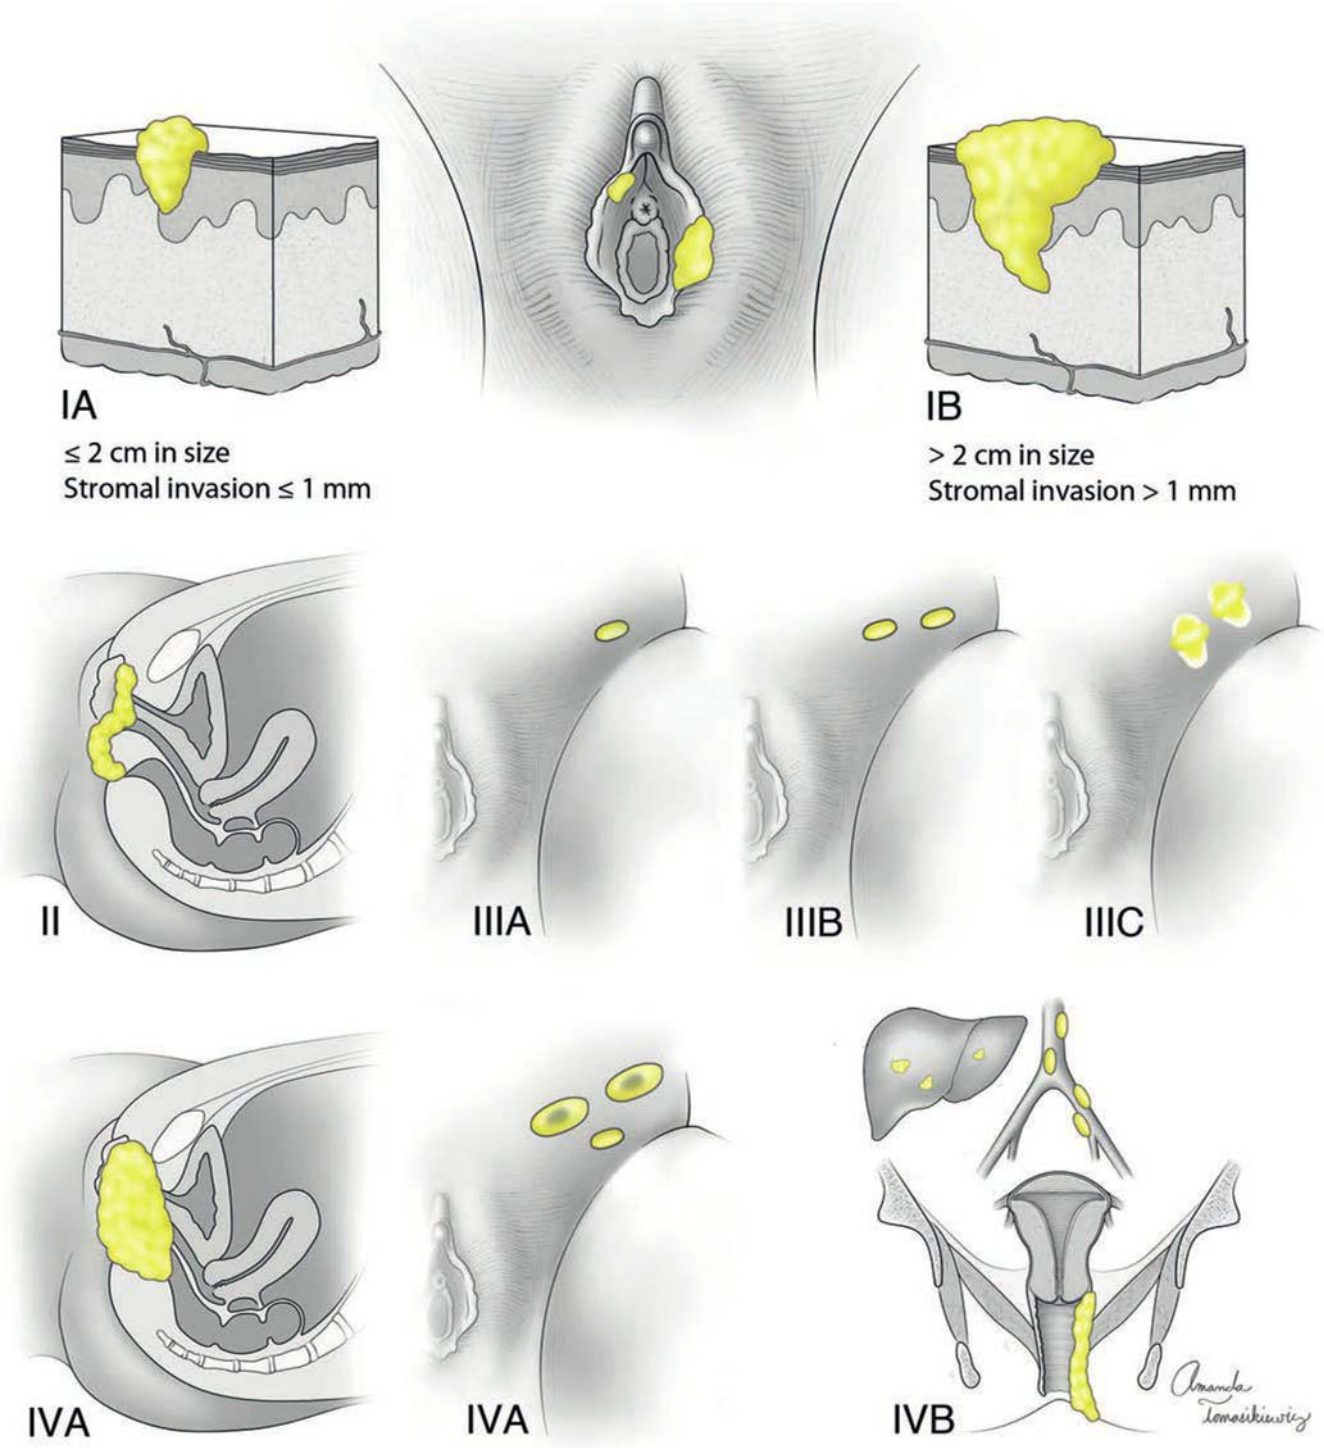

FIGURE 31-5 FIGO (International Federation of Gynecology and Obstetrics) staging of invasive vulvar cancer.

Figge, 1985). Nodal status is determined by sentinel lymph node biopsy or lymphadenectomy and histologic evaluation. Among patients with nodal metastasis, other factors further predict poor prognosis. These include a high number of involved lymph nodes, large nodal metastasis size, extracapsular invasion, and fixed or ulcerated nodes (Homesley, 1991; Origoni, 1992).

Tumor diameter also influences survival rates. But this stems mainly from the positive correlation between lesion size and nodal metastasis rates (Homesley, 1993).

Depth of invasion is another prognostic element. This depth is measured from the epidermis basement membrane to the deepest point of invasion into the dermis and subcutaneous layer (Kurman, 2014). Tumors with a depth of invasion <1 mm carry little or no risk of inguinal lymph node metastasis. However, depth of invasion positively correlates with increased nodal metastasis.

Surgical margins that are tumor-free lower local tumor recurrence rates. Thus, at a minimum, a 2-cm tumor-free margin is

TABLE 31-3. Prognostic Predictors

Depth of Invasion (mm)	Positive Nodes (%)
1	3
2	9
3	19
4	31
5	33
≥5	48

Tumor Diameter (cm)	5-Year Survival (%)	Groin Nodes Positive (%)
0–1	90	18
1–2	89	19
2–3	83	31
3–4	63	54
>4	44	40–52

Abbreviated from Homesley, 1993; Stehman, 2006.

desired. More specifically, two large retrospective series demonstrated that a tumor-free surgical margin ≥8 mm at final pathologic analysis yielded a high rate of local control. In contrast, if tumor was found within this 8-mm margin, the recurrence rate was 23 to 48 percent (Chan, 2007; Heaps, 1990). Other studies have failed to confirm that a minimum margin of 8 mm is necessary to reduce local recurrence (Nooij, 2016; Woelber, 2016). However, tumor-positive margin status is a consistent independent risk factor for disease recurrence. Reexcision or adjuvant radiotherapy is indicated when margins are positive for cancer. Management of patients with narrow tumor-free margins is controversial. There is no clear consensus on the prognostic value of a specific tumor-free margin threshold. Therefore, observation or adjuvant radiation can be considered for narrow tumor-free vulvar margins to prevent cancer recurrence. When lesions are close to the clitoris, anus, urethra, or vagina, we recommend aiming for margins sufficiently wide to preserve important anatomic function.

Lymphatic vascular space invasion (LVSI) describes histologic identification of tumor cells within lymphatic vessels and is a predictor of early disease recurrence (Preti, 2005). LVSI is also associated with a higher frequency of lymph node metastasis and a lower overall 5-year survival rate (Hoskins, 2000).

Perineural invasion is also a poor prognostic indicator for women diagnosed with vulvar cancer. Patients with perineural invasion have a higher likelihood of lymph node involvement, advanced cancer stage, and LVSI. They also have worse progression-free and overall survival rates (Salcedo, 2019).

TREATMENT

Surgery

Surgery is often an integral part of vulvar cancer treatment. Potential procedures, in increasing order of radicality, include wide local excision, radical partial vulvectomy, and radical total vulvectomy.

Wide local excision can be appropriate for preinvasive disease and microinvasive tumors (stage IA) of the vulva and some rare histologic types. With this excision, also termed *simple partial vulvectomy*, a 1-cm surgical margin is obtained around the lesion. Deep surgical margins measuring 1 cm also are preferred. This deep margin usually corresponds to Colles fascia (Fig. 38-26, p. 815).

With *radical partial vulvectomy* (Chap. 46, p. 1235), tumor-containing portions of the vulva are completely removed, wherever they are located. Skin margins are ideally 2 cm, and excision extends deep to the perineal membrane (Fig. 31-6). Radical partial vulvectomy is typically reserved for lesions that are not too large or extensive, with an otherwise normal vulva.

Radical total vulvectomy (Chap. 46, p. 1238) is a complete dissection of vulvar tissue to the level of the perineal membrane and the periosteum of the pubic rami or symphysis. Adequate

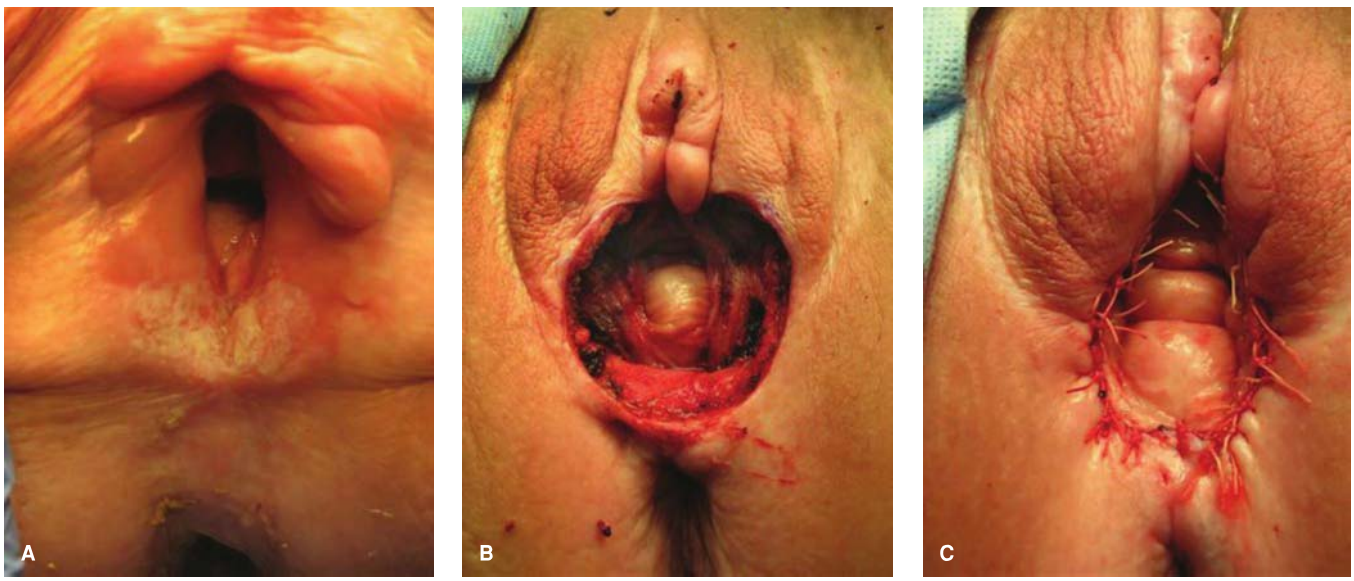

FIGURE 31-6 **A.** Vulvar cancer following radiation therapy and in preparation for surgical excision. **B.** Radical partial vulvectomy. **C.** Primary surgical closure. (Reproduced with permission from Dr. David Miller.)

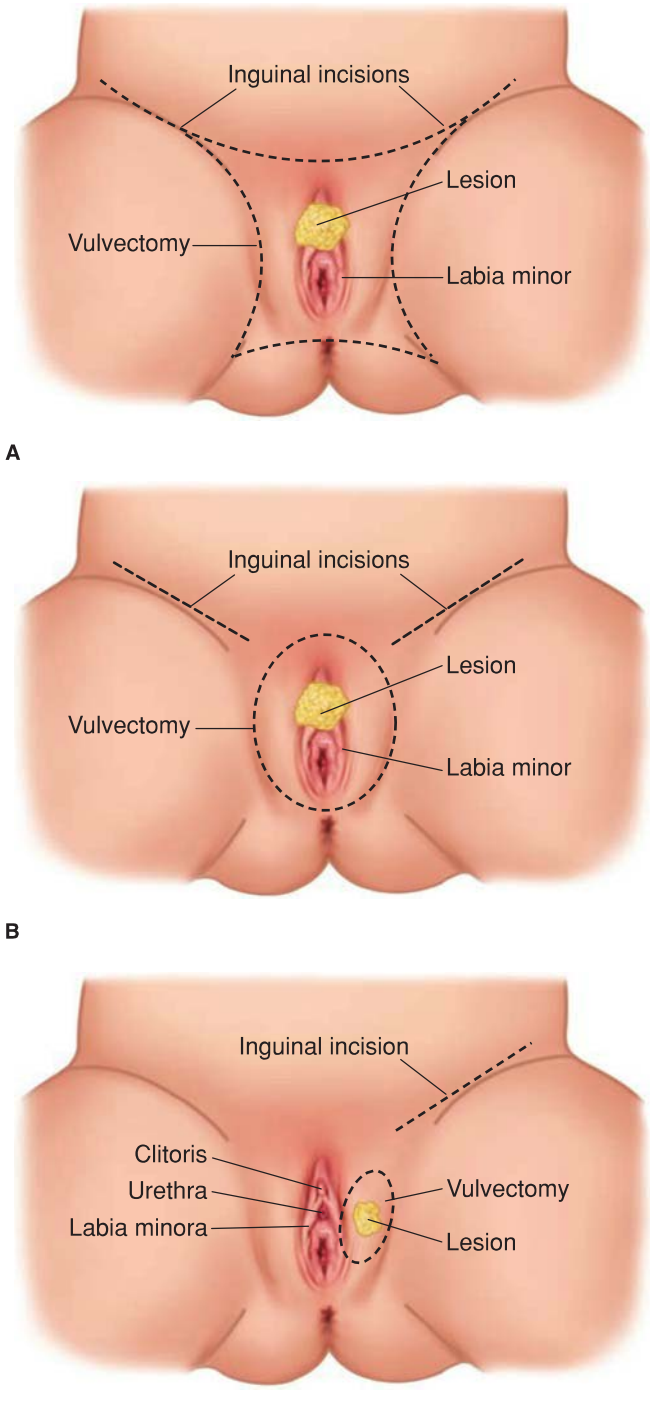

FIGURE 31-7 Types of vulvectomy used in the treatment of vulvar cancer. **A.** En bloc radical vulvectomy with bilateral inguinofemoral lymphadenectomy. **B.** Radical total vulvectomy with bilateral inguinofemoral lymphadenectomy. **C.** Radical partial vulvectomy with ipsilateral inguinofemoral lymphadenectomy.

margins will generally require an incision in the labiocrural fold that extends down to the fourchette and up over the mons pubis (Figure 31-7). All intervening subcutaneous tissue is excised. Lesions involving or adjacent to the clitoris may require wider margins cephalad to the mons. Such radical resections are performed for large midline or multifocal vulvar cancers. Flap reconstruction is occasionally needed and described in Chap. 46, (p. 1244). Contraindications to a radical total vulvectomy include poor surgical risk, poor patient compliance, and metastatic disease beyond regional lymph nodes.

Of the three procedures shown in Figure 31-7, the en bloc incision, colloquially termed the *butterfly* or *longhorn* incision, has largely been abandoned. It has survival rates equivalent to radical total vulvectomy but carries significantly greater morbidity.

Inguinofemoral Lymphadenectomy

This procedure is usually an integral part of surgical cancer staging and accompanies radical partial or radical total vulvectomy for squamous cell carcinoma of the vulva. It is recommended for all vulvar squamous carcinomas that invade deeper than 1 mm on initial biopsy or that have a tumor diameter >2 cm regardless of invasion depth (stages IB-IVA). To maximize metastatic disease detection and staging accuracy, surgical evaluation of the inguinal nodes is recommended. Traditionally, both the superficial inguinal and deep femoral lymph nodes have been removed for evaluation of metastatic disease (Gordinier, 2003). Moreover, lymph nodes may be excised unilaterally or bilaterally. Traditionally, an ipsilateral inguinofemoral lymphadenectomy is performed for a "lateralized" vulvar lesion, namely, one that lies >2 cm beyond the midline. Bilateral node excision is recommended for all midline lesions and lesions within 2 cm of the midline. Aside from acquiring staging information, inguinofemoral lymphadenectomy may also be used to debulk large, cancerous lymph nodes.

Entire steps for lymphadenectomy are described and illustrated in Chapter 46 (p. 1241). To summarize, the superficial inguinal lymph nodes lie within the fatty tissue caudal to the inguinal ligament and superficial to the thigh's fascia lata. This node-containing tissue is dissected free to reach the fossa ovalis. Here, deep femoral nodes are excised from their location medial to and alongside the femoral vein. For these deep nodes, a modified approach preserves the cribriform fascia (portion of fascia lata overlying the fossa ovalis) by removing the deep femoral nodes through the cribriform fascia's perforations. This modification yields cancer recurrence rates comparable to those obtained following classic inguinofemoral node dissection (Bell, 2000; Hacker, 1983). Advantageously, complication rates of wound breakdown, infection, and lymphedema are significantly lower (Table 31-4). However, a classic inguinofemoral node dissection is occasionally required to reach these deep femoral lymph nodes. In such cases, the cribriform fascia is transected, lymph nodes are removed, and the sartorius muscle

TABLE 31-4. Postoperative Complications of Inguinofemoral Lymphadenectomy

Complication	No. of Events	Percent of Groins
Lymphedema	13	14.0
Lymphocele	11	11.8
Groin infection	7	7.5
Groin necrosis	2	2.2
Groin separation	7	7.5

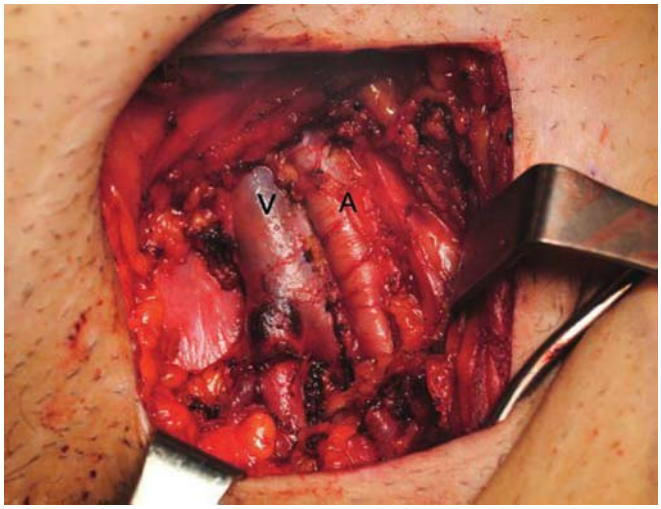

FIGURE 31-8 Surgical photography during inguinofemoral lymphadenectomy. Here, the cribriform fascia has been excised and nodes have been removed. The femoral vein (*V*) and artery (*A*) are marked. (Reproduced with permission from Dr. Matthew Carlson.)

can then be transposed over the femoral vessels (Fig. 31-8). This transposition may reduce the risk of postoperative erosion into the skeletonized and thus more exposed femoral vessels if superficial wound dehiscence occurs. However, this transposition does not reduce overall postoperative wound morbidity rates (Judson, 2004; Rouzier, 2003).

Inguinal femoral lymphadenectomy versus primary radiation therapy in patients with clinically negative nodes is controversial. Surgical evaluation of the groin nodes has been reported to confer a superior prognosis compared with primary groin irradiation in some studies. One study by the Gynecologic Oncology Group (GOG) showed that patients undergoing primary inguinal node dissection experienced significantly fewer groin recurrences and a better prognosis compared with women receiving groin irradiation (Stehman, 1992). In other studies, a higher than acceptable groin recurrence rate after primary groin irradiation has been supported but also challenged (Hallack, 2007; Manavi, 1997; Perez, 1993; Petereit, 1993). At our institution, surgical evaluation of one or both groins is performed if the patient is a reasonable surgical candidate. In general, both deep and superficial inguinal lymph node removal is performed to allow thorough evaluation for nodal metastasis in women with tumor diameter ≥4 cm. Sentinel lymph node biopsy is used in vulvar lesions <4 cm in diameter.

Sentinel Lymph Node Biopsy

As one less morbid option, selective dissection of a solitary node or nodes, termed *sentinel lymph node biopsy (SLNB)*, dramatically reduces surgical morbidity yet adequately assesses nodal involvement. Physiologically, the first lymph node to receive tumor lymphatic drainage is termed the *sentinel lymph node*. Thus, a sentinel lymph node devoid of disease implies absent lymph node metastases within the entire lymph node basin. SLNB is not performed if groin node metastases are clinically suspected.

Currently, both lymphoscintigraphy and isosulfan blue dye techniques are recommended when performing SLNB for vulvar cancer (Levenback, 2008). To begin, intraoperative lymphatic mapping is accomplished by injecting radionuclide intradermally at the tumor border that lies closest to the ipsilateral groin. For midline tumors, both sides of the tumor are injected. A handheld gamma counter aids attempts to identify the sentinel node subcutaneously, and the skin is marked by pen over the strongest signal. Next, isosulfan blue dye is injected at the same tumor border, and the groin skin over the prior pen mark is incised approximately 5 minutes later (Fig. 31-9). The tracer and dye are taken up by the specific node that drains the tumor site first. The sentinel node may be localized by the handheld gamma counter signal, and/or it can be visually isolated by its blue color. Once identified, it is separated and excised from the other nodes within that regional group.

Several studies have confirmed the accuracy of SLNB to predict vulvar cancer metastasis in the inguinal lymph nodes in select patients. One trial by the GOG reported the sensitivity of this technique exceeded 90 percent, and the false negative predictive value was 2 percent for tumors measuring <4 cm in diameter (Frumovitz, 2005).

A second study, the GROningen International Study on Sentinel nodes in Vulvar cancer (GROINSS-V), evaluated SLNB

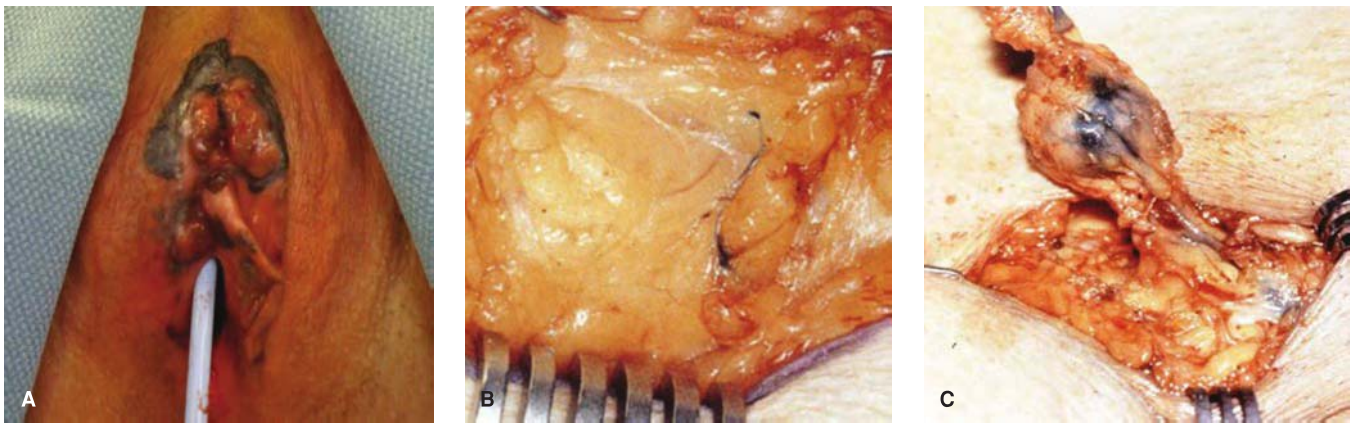

FIGURE 31-9 Sentinel lymph node evaluation. **A.** Blue dye and radiotracer are injected at the tumor periphery. **B.** Blue dye is taken up by the specific node that drains the tumor site. **C.** This sentinel node can be visually identified, separated from the other nodes within the regional group, and removed for evaluation.

for patients with unifocal squamous cell cancer of the vulva measuring <4 cm. It too confirmed the satisfactory false negative predictive value of SLNB (2.9 percent). The isolated groin recurrence rate was 2.5 percent in sentinel node–negative patients, and all groin recurrences were identified within 16 months after primary treatment (Te Grootenhuis, 2016). Last, although results are pending, the completed GROINSS-V-II study (GOG protocol 270) observed early-stage vulvar cancer patients with a sentinel node metastasis measuring ≤2 mm to see if complete inguinofemoral lymphadenectomy can be safely replaced by adjuvant radiotherapy following vulvectomy.

Microinvasive Tumors (Stage IA)

Within the FIGO system, stage I vulvar cancers are divided into two categories. Stage IA lesions measure ≤2 cm in diameter, are confined to the vulva or perineum, and display stromal invasion ≤1 mm. These lesions, termed *microinvasive cancers*, reflect a subpopulation in which the risk of inguinal metastasis is negligible (Binder, 1990; Donaldson, 1981; Hacker, 1984). Women with microinvasive stage IA tumors tend to be younger and have multifocal disease associated with HPV. For probable cure, these patients can undergo wide local excision with a 1-cm margin. Lymphadenectomy is not indicated because associated lymph node metastasis is rare.

Stage IB–II

Patients with early-stage vulvar cancer typically present with T1B and T2 lesions (stage IB and II) of the vulva and clinically negative groin nodes. For stage IB lesions, radical resection of the primary tumor and inguinofemoral lymphadenectomy is recommended. If adequate margins and dissection to the perineal membrane can be achieved, then radical partial vulvectomy offers similar recurrence rates but less morbidity than radical total vulvectomy (Tantipalakorn, 2009). Because 20 to 30 percent of women with T1 and T2 disease will have diseased nodes, SLNB and/or inguinofemoral lymphadenectomy is performed. Described earlier, lesion laterality and clinical impression regarding groin involvement guides the decision to perform ipsilateral or bilateral groin dissection (p. 682).

Stage II cancers are most often managed with a larger radical partial excision. For example, a 4-cm lesion involving the clitoral hood may be managed by an anterior hemivulvectomy and bilateral inguinofemoral lymphadenectomy. Again, reported experience with conservative surgery suggests identical local recurrence rates if 1- to 2-cm tumor-free surgical margins are achieved (Burke, 1995; Farias–Eisner, 1994; Tantipalakorn, 2009). Occasionally, a radical total vulvectomy may be required, depending on tumor size and location.

Stage III

By definition, stage III vulvar cancers include node-positive tumors. Affected patients have T1 or T2 vulvar lesions and involved regional lymph nodes that are not fixed or ulcerated. Most patients with clinically negative nodes typically undergo a radical partial or total vulvectomy and either SLNB or inguinofemoral lymphadenectomy. For cases in which groin nodes are grossly positive and resectable, inguinofemoral lymphadenectomy is performed. Most women with stage III vulvar cancer also receive postoperative adjuvant radiation directed to both groins and the pelvis. Efficacy for this was shown in a randomized GOG trial of 114 patients with invasive squamous cell carcinoma of the vulva and diseased groin nodes. Adjuvant radiation to both groins and the pelvic midplane following lymphadenectomy proved superior to extended pelvic node resection. However, 12 percent of women completing radiotherapy still relapsed in the groin and pelvis, and 8.5 percent at distant sites (Homesley, 1986; Kunos, 2009).

Evidence that nodal metastasis raises the risk of recurrence on the vulva is inconclusive. Hence, adjuvant vulvar radiation is the treating physician's decision and guided by margin status and tumor size and location.

Stage IVA

These locally advanced vulvar cancers involve the proximal urethra, proximal vagina, bladder or rectal mucosa, or pelvic bone and may or may not have affected inguinal lymph nodes (Fig. 31-10). With stage IVA vulvar cancers, women occasionally can be treated with radical primary surgery. Much more often, tumor size and location necessitate some form of exenterative surgical procedure to remove the entire lesion with adequate margins. Such poorly resectable, locally advanced vulvar cancers can be effectively treated with neoadjuvant chemoradiation to drastically minimize the surgical resection required. Two GOG studies GOG have demonstrated the feasibility of this approach using cisplatin regimens (Moore, 1998, 2012). An ongoing phase II trial is currently evaluating the efficacy of cisplatin, gemcitabine, and intensity-modulated radiation therapy (IMRT) for primary treatment of locally advanced squamous cell carcinoma of the vulva. Described in Chapter 28 (p. 612), IMRT offers greater sculpting of radiation delivery to minimize toxicity.

Our current practice is to offer preoperative cisplatin-based chemoradiation to women with inoperable primary tumors or with extensive lesions that would require pelvic exenteration. In

FIGURE 31-10 Locally advanced vulvar cancer that is a candidate for primary radiation therapy. (Reproduced with permission from Dr. William Griffith.)

cases without fixed groin nodes, pretreatment inguinofemoral lymphadenectomy is performed to determine the need for groin irradiation. If groin nodes are fixed or ulcerated, then primary chemoradiation is administered to treat these involved nodes.

If residual disease remains on the vulva following chemoradiation, then local resection is indicated. If the clinical response appears complete, the primary tumor site undergoes excisional biopsy to confirm pathologic response. Unresected groins that are clinically or radiographically positive 8 weeks after surgery are biopsied by fine-needle aspiration (FNA). If the FNA is positive, a targeted excision of the groin is performed.

In contrast, for stage IVB vulvar cancer, treatment is individualized. A multimodal approach that may include chemotherapy and radiation may be used for palliation.

SURVEILLANCE

After completing primary treatment, all patients receive thorough physical examination that includes inguinal lymph node palpation and pelvic examination every 3 months for the first 2 to 3 years. Surveillance examinations are then scheduled every 6 months to complete a total of 5 years. Thereafter, disease-free women may be seen annually (Salani, 2017). Biopsies are performed if concerning areas are noted. Radiologic imaging and targeted biopsies to diagnose possible tumor recurrence are completed as indicated.

RECURRENT DISEASE

Vulvar Recurrences

For women with local tumor recurrence, the 5-year survival rate is 67 percent. This compares with a rate >80 percent in women with no recurrence (Woelber, 2016). In a woman with suspected recurrence, careful evaluation helps define disease extent. Local vulvar recurrences are most common, and surgical reexcision is usually the best option. Radical partial vulvectomy is appropriate for smaller lesions. Patients who had SLNB during primary treatment and who have not previously received groin irradiation are candidates for concurrent inguinofemoral lymphadenectomy at the time of local recurrence resection. If a patient has received prior vulvar radiation, those with large central recurrences involving the urethra, vagina, or rectum may require a total pelvic exenteration with reconstructive surgery (Chap. 46, p. 1174).

With exenteration, to maintain sexual function, vaginal reconstruction can be completed at the time of surgery or after a short postoperative interval (Chap. 46, p. 1190). Radiated tissue often has a poor blood supply. Thus, vulvar recurrences in a previously radiated field typically require myocutaneous flaps for reconstruction after surgical resection. Last, for patients who are not surgical candidates but are radiation naïve to the vulva, external beam radiation combined with interstitial brachytherapy can be an option.

Distant Recurrences

Inguinal lymph node recurrences are virtually always associated with ultimately fatal disease, and few women are alive at the end of the first year following this diagnosis. Women with pelvic or distant metastases can be offered palliative chemotherapy. Combination platinum-based chemotherapy has modest activity in recurrent vulvar cancers (Cunningham, 1997; Moore, 1998). Platinum-based regimens (e.g., cisplatin/paclitaxel) might be considered for vulvar cancer if palliative chemotherapy is indicated.

MANAGEMENT DURING PREGNANCY

Squamous cell cancer of the vulva diagnosed and surgically treated during pregnancy is rare, and an incidence of 1 per 20,000 deliveries is reported (DiSaia, 1997). Nevertheless, any suspicious lesion is evaluated, even during pregnancy.

Radical total or partial vulvectomy and inguinofemoral lymphadenectomy can be performed if indicated after the first trimester. During the third trimester, markedly increased genital vasculature can raise surgical morbidity. During the late third trimester, lesions may be removed by wide local excision, and definitive surgery completed postpartum. In cases diagnosed at delivery, definitive surgery is performed typically 2 to 3 weeks postpartum.

The mode of delivery following cancer surgery is heavily influenced by the state of the postsurgical vulva. With vaginal stenosis, significant fibrosis, or tumor involvement, a cesarean delivery is recommended. Otherwise vaginal delivery is appropriate.

VERRUCOUS CARCINOMA

This rare variant of squamous cell carcinoma constitutes <1 percent of all vulvar cancers. Verrucous carcinomas can affect both younger and older women. Its etiology is unknown, but HPV genome and usual type VIN are found in association with some of these tumors. Verrucous carcinomas are locally invasive and rarely metastasize. Most women have a cauliflower-shaped vulvar mass that usually elicits pruritus or pain. Surgery is preferred, and most tumors are excised by wide local excision that ensures a 1-cm surrounding margin. Inadequate margins risk local recurrence. Verrucous carcinomas are resistant to radiotherapy and if exposed may undergo anaplastic transformation to become more aggressive and invasive. Enlarged groin lymph nodes are evaluated preoperatively by FNA because they usually are inflammatory.

MELANOMA

Clinical Presentation and Staging

Melanoma is the second most common vulvar cancer and accounts for 10 percent of all vulvar malignancies. Vulvar melanoma disproportionately affects the elderly and develops more often among whites. Vulvar melanoma has an overall poor prognosis, and 5-year survival rates range from 8 to 55 percent (Evans, 1994; Piura, 1992).

Malignant vulvar melanomas most frequently arise from the labia minora, labia majora, or clitoris (Fig. 31-11) (Moore, 1998; Woolcott, 1988). Some benign pigmented lesions also can be found here and include lentigo simplex, vulvar melanosis, acanthosis nigricans, seborrheic keratosis, and nevi (Chap. 4, p. 101). Last, pigmented vulvar neoplasia may be VIN, squamous cell carcinoma, or Paget disease. Thus, tissue sampling is typically needed, and immunohistochemical studies or electron microscopy can

FIGURE 31-11 Vulvar melanoma. (Reproduced with permission from Dr. William Griffith.)

help clarify the diagnosis (Fig. 31-12). Three histologic subtypes of vulvar melanoma are described: superficial spreading melanoma, nodular melanoma, and acral lentiginous melanoma.

Vulvar melanomas have been staged by several microstaging systems that include the Chung, the Clark, and the Breslow systems and by the macroscopic systems published by FIGO and the American Joint Committee on Cancer (AJCC) (Table 31-5). The AJCC stage and Breslow thickness are major predictors of overall survival rates and are used most often. Breslow thickness measures in millimeters the thickest portion of the lesion from the intact epithelium's most superficial surface to the deepest point of invasion (Moxley, 2011; Verschraegen, 2001).

Treatment

Surgery

Vulvar melanoma has limited response to both chemotherapy and radiotherapy. Thus, excision is the single best definitive therapy. Conservative surgery, such as wide local excision or a radical partial vulvectomy, is preferred as radical surgery appears to offer no greater survival advantage (Irvin, 2001; Verschraegen, 2001).

Nodal metastasis is a major predictor of prognosis. The incidence of occult inguinal lymph node metastases is <5 percent for thin melanomas measuring <1 mm thickness but is >70 percent for lesions >4 mm (Hoskins, 2000). Women with clinically positive groin lymph nodes should undergo inguinofemoral lymphadenectomy if possible, as surgical removal of regional disease is the most effective method of control. In patients with clinically negative groins, the decision to perform inguinofemoral lymphadenectomy or SLNB is influenced by lesion thickness. Primary lesions that warrant inguinofemoral node evaluation are those that have a Breslow thickness >1 mm. Other high-risk candidate tumors are those lesions measuring <1 mm thick but showing ulceration, a mitotic rate >1 per mm^2, or LVSI. Another high-risk lesion is that with ambiguous thickness due to a biopsy's positive deep margin (Lens, 2002b). At our institution, we encourage women with clinically negative groins to first undergo SLNB. If diseased nodes are detected, then an inguinofemoral lymphadenectomy can be considered. Primary radiation therapy can be considered as palliative for patients with advanced vulvar melanoma who are either unfit or unwilling to undergo surgery.

Adjuvant Therapy

Women may be considered for adjuvant therapy if their primary vulvar melanoma poses a great risk for disease recurrence. These risk factors include positive margins or positive inguinofemoral nodes. Although melanomas were once felt to be radioresistant, adjuvant radiation therapy can be considered for local control (Ballo, 2005; Moxley, 2011).

Previously, adjuvant alpha interferon (IFN-α) was recommended for patients with high-risk cutaneous melanoma due to an increase in both progression-free and overall survival rates (Lens, 2002a). Now, biologic antitumor agents offer superior tumor control. Of these, ipilimumab (Yervoy), a cytotoxic T

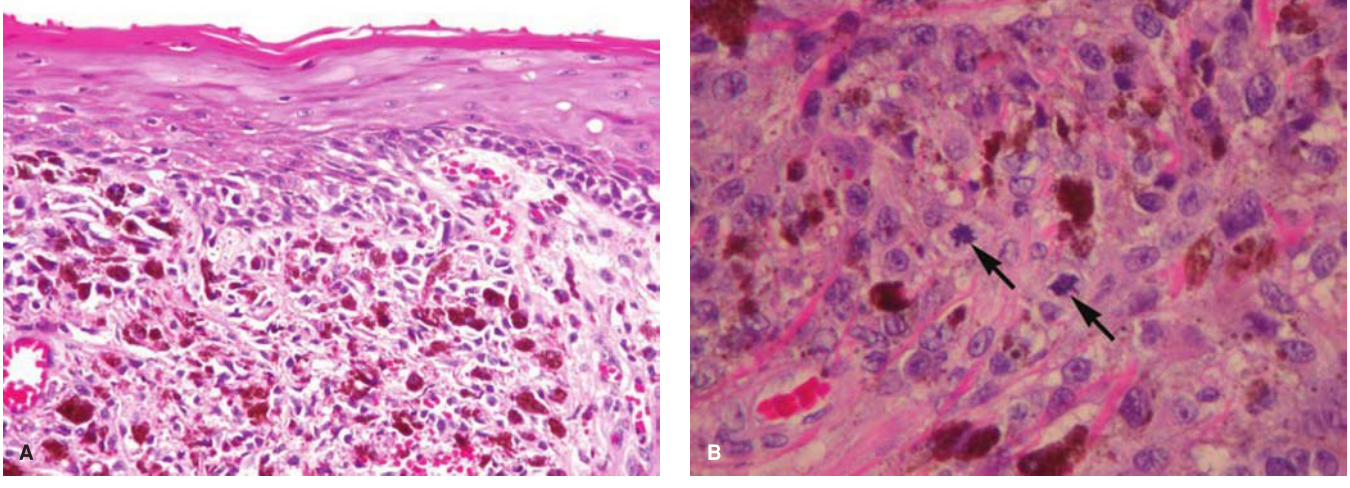

FIGURE 31-12 Vulvar melanoma. **A.** Medium-power view. Atypical, hyperchromatic melanoma cells are identified within the basal portion of the surface epithelium. Melanoma cells containing intracytoplasmic melanin pigment invade subepithelial stroma in a broad swath. **B.** High-power view. The malignant melanoma cells in this case have occasionally prominent nucleoli, abundant intracytoplasmic melanin pigment, and frequent mitoses (*arrows*) including abnormal mitoses. Summarized from Balch, 2009.

lymphocyte–associated protein 4 (CTLA4) checkpoint inhibitor, was subsequently recommended instead of IFN-α due to the magnitude of overall survival benefit (Eggermot, 2015). Currently, adjuvant treatment with nivolumab (Opdivo), a programmed cell death protein 1 (PD-1) checkpoint inhibitor, can be considered in patients with stage III or IV vulvar melanoma. Its mechanism is illustrated in Chapter 27 (p. 601). Nivolumab prolonged disease-free survival compared with ipilimumab in one trial of 906 patients with acral, mucosal, or cutaneous melanoma (McDermott, 2019).

Targeting key driver mutations is another option for metastatic melanoma. Namely, *BRAF* and *c-KIT* gene mutations may be found in these tumors, and women with melanoma often have their tumors tested for these mutations. Vemurafenib (Zelboraf), a BRAF inhibitor, was approved by the Food and Drug Administration (FDA) for treatment of metastatic or unresectable melanoma that exhibits the *BRAF* mutation (Robert, 2011). Imatinib (Gleevec) may be used for tumors with the *c-KIT* mutation.

BASAL CELL CARCINOMA

Basal cell carcinoma of the vulva accounts for <2 percent of all vulvar cancers and is most commonly found in elderly women (DiSaia, 1997). Lesions typically arise on the labia majora and are characterized by poor pigmentation and pruritus. They often mimic eczema, psoriasis, or intertrigo. As a result, correct diagnosis is often delayed due to treatment for other presumed inflammatory or infectious dermatoses.

Although ultraviolet radiation is thought to be the primary risk factor for basal cell carcinoma on sun-exposed areas, its development on sun-protected areas raises the possibility of other, yet undefined, etiologies. Some suggest that local trauma and advancing age may contribute at these sites (LeSueur, 2003; Wermuth, 1970).

Basal cell carcinoma is removed by radical partial vulvectomy using a minimum surgical margin of 1 cm. Lymphatic or distant spread is rare, but inguinofemoral lymphadenectomy or SLNB is considered for clinically suspicious nodes. However, disease may locally recur, particularly in tumors removed with suboptimal margins. Most basal cell carcinomas of the vulva are indolent and locally invasive but rarely metastatic. If surgery is contraindicated, then primary radiation therapy can be considered. Local immunomodulators such as imiquimod can be selected for patients who are inappropriate surgical candidates. Because surgery is the recommended treatment, any other treatment modalities will warrant close observation to detect cancer progression.

VULVAR SARCOMA

Sarcoma of the vulva is rare, and leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, and malignant rhabdoid tumor are the more frequently encountered histologic types. Of these, leiomyosarcoma appears to be most common. Tumors typically develop as isolated masses on the labia majora, clitoris, or Bartholin gland (Fig. 31-13). Unlike squamous cell carcinoma, the age of affected women is significantly broader and varies between histologic types.

The outcome of vulvar sarcomas is influenced by tumor size, degree of mitotic activity, and level of infiltration. That is, disease associated with lesions >5 cm in diameter, with infiltrating margins, with extensive necrosis, and with more than five mitoses per 10 high-power fields is most likely to recur after surgical resection (Magné, 2011).

Hematogenous metastasis is the most frequent route of tumor dissemination. Radical partial or total vulvectomy or pelvic exenteration is recommended if total surgical resection is possible. Removal of inguinofemoral lymph nodes is performed if nodes are large and/or symptomatic. Adjuvant radiation, chemotherapy, or both can be considered depending on risk factors for recurrence. Neoadjuvant chemotherapy and/or radiotherapy are considerations for unresectable vulvar sarcomas.

BARTHOLIN GLAND CARCINOMA

Primary malignant tumors arising from the Bartholin gland can be adenocarcinomas, squamous cell carcinomas, or transitional cell carcinomas. The incidence of Bartholin gland carcinomas peaks in women in their mid-60s. Soft, distensible tissue normally surrounds these glands, and tumors may reach considerable size before patients develop symptoms. Dyspareunia is a common first complaint. Bartholin gland enlargement in a woman older than 40 years and recurrent cysts or abscesses

FIGURE 31-13 Vulvar epithelioid sarcoma.

warrant a biopsy or excision. Similarly, all solid masses require FNA or biopsy to establish a definitive diagnosis.

Bartholin gland carcinomas tend to spread into the ischiorectal fossa and have a propensity for lymphatic spread into the inguinal and pelvic lymph nodes. Therapy for most early cancer stages includes a radical partial vulvectomy with inguinofemoral lymphadenectomy. Decisions to perform ipsilateral or bilateral groin dissection follow the same criteria as for squamous cell tumors. Postoperative chemoradiation reduces the likelihood of local recurrence for all stages. If the initial lesion impinges on the rectum or anal sphincter, preoperative chemoradiation can be used to avoid extensive surgery.

VULVAR PAGET DISEASE

Extramammary Paget disease is a heterogeneous group of intraepithelial neoplasias and, when present on the vulva, appears as an eczematoid, red, weeping area (Fig. 31-14). These

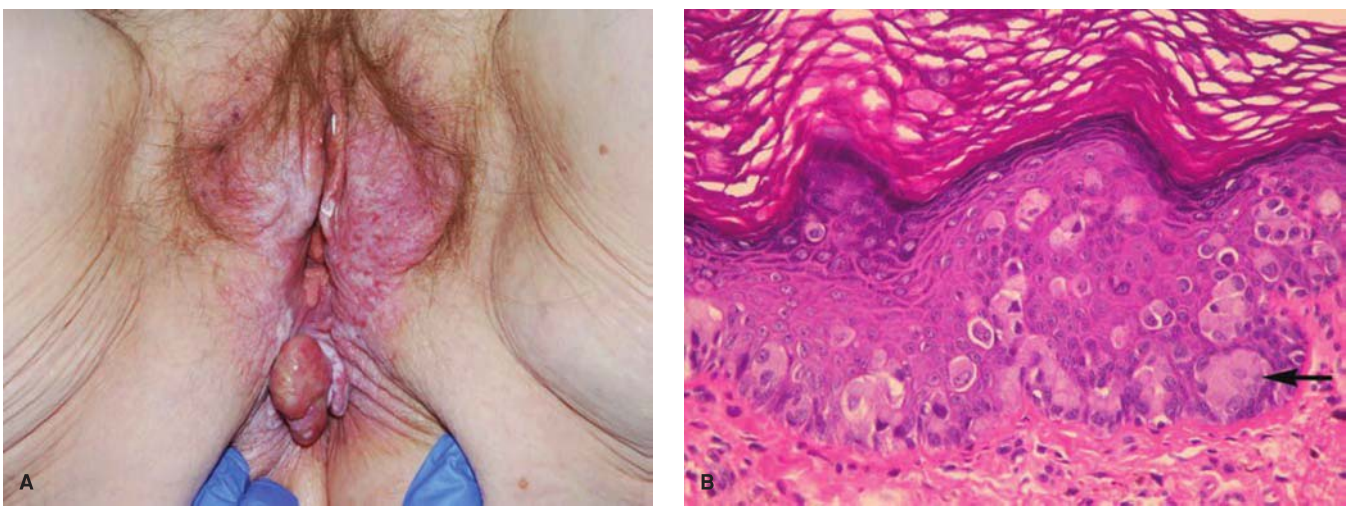

FIGURE 31-14 A. Vulvar Paget disease involving the labia bilaterally, perineum, perianus, and solid right perianal mass. (Reproduced with permission from Dr. Claudia Werner.) **B.** Photomicrograph of primary cutaneous vulvar Paget disease. This is characterized microscopically by the presence of relatively large atypical cells with prominent nucleoli and abundant delicate cytoplasm (*arrow*). These cells are disposed singly or in clusters at various levels within the epithelium. The neoplastic cells are most often confined to the epithelium and would in these instances be classified as an adenocarcinoma in situ. (Reproduced with permission from Dr. Kelley Carrick.)

are often localized to the labia majora, perineal body, or clitoris. This disease typically develops in older white women and accounts for approximately 2 percent of all vulvar tumors. Vulvar Paget disease is accompanied by invasive Paget disease or adenocarcinoma of the vulva in 10 to 20 percent of cases (Hoskins, 2000). Moreover, 20 percent of patients with extramammary Paget disease of the vulva will have a carcinoma at another nonvulvar location (Pang, 2010; Wilkinson, 2002). Screening and surveillance for tumors at nongynecologic sites is considered and includes evaluation of the breasts and the gastrointestinal and genitourinary tracts. A discussion of Paget disease of the breast is presented in Chapter 13 (p. 290).

A histologic classification proposed by Wilkinson and Brown (2002) includes: (1) primary vulvar cutaneous Paget disease, (2) Paget disease as an extension of transitional cell carcinoma of the bladder or urethra, and (3) Paget disease as an extension of an associated adjacent primary cancer such as vulvar, anal, or rectal cancers. The histologic differentiation of these Paget disease types is important because the specific diagnosis significantly influences treatment selection.

Of these, primary cutaneous vulvar Paget disease displays slow growth. Diseased areas ideally are resected by wide local excision with a 1- to 2-cm margin. In contrast to resected VIN 3, margins are often positive, and disease recurrence develops frequently regardless of the surgical margin status (Black, 2007). Long-term surveillance is prudent since repeated surgical excision is often necessary. Patients with positive margin after surgical excision of the primary tumor can be followed conservatively.

If invasive disease is suspected, radical partial vulvectomy is warranted by extending the deep margins to the perineal membrane. The latter is frequently accompanied with an ipsilateral or bilateral inguinofemoral lymphadenectomy.

CANCER METASTATIC TO THE VULVA

Metastatic tumors make up approximately 8 percent of all vulvar cancers. Tumors may extend from primary cancers of the bladder, urethra, vagina, or rectum. Less proximate cancers include those from the breast, kidney, lung, and stomach, as well as gestational choriocarcinoma (Wilkinson, 2011).

SQUAMOUS CELL CARCINOMA 691
ADENOCARCINOMA 695
MESENCHYMAL TUMORS 695
MELANOMA 696
REFERENCES 697

Cancer found in the vagina is most likely metastatic disease. Primary vaginal carcinoma is rare and makes up less than 5 percent of all gynecologic malignancies (Siegel, 2019). This low incidence reflects the infrequency with which primary carcinoma arises in the vagina and the strict criteria for its diagnosis. According to International Federation of Gynecology and Obstetrics (FIGO) staging criteria, a vaginal lesion that involves adjacent organs such as the cervix or vulva, by convention, is deemed primary cervical or vulvar, respectively (Pecorelli, 1999). The most common histologic type of primary vaginal cancer is squamous cell carcinoma, followed by adenocarcinoma (Platz, 1995).

RELEVANT ANATOMY

During embryogenesis, the müllerian ducts fuse caudally to form the uterovaginal canal (Chap. 19, p. 406). The canal's distal portion forms the proximal vagina, whereas the distal vagina arises from the urogenital sinus. The uterovaginal canal is lined by columnar epithelium, which is subsequently replaced by squamous cells migrating cephalad from the urogenital sinus. These squamous cells stratify, and the vaginal epithelium matures and thickens. Underlying this epithelium, muscularis and adventitial layers surround the vaginal tube.

With vaginal cancer, local extension and lymphatic invasion are common patterns of spread. The lymphatic channels that drain the vagina form extensive, complex, and variable anastomoses. As a result, any node in the pelvis, groin, or anorectal area may drain any part of the vagina. Of these, the external, internal, and common iliac lymph nodes are the primary sites of vaginal lymphatic drainage. Thus, pelvic lymphadenectomy, which samples these nodal groups, is commonly performed during primary surgical excision of proximally located vaginal cancers. Alternatively, lymphatic vessels of the posterior vagina may empty into the inferior gluteal, presacral, or perirectal nodes, and those of the vagina's distal third may drain to the superficial and deep inguinal lymph nodes (Frank, 2005).

Hematogenous spread of vaginal cancer is less frequent, and venous drainage consists of the uterine, pudendal, and rectal veins, which drain into the internal iliac vein. Arterial blood supply to the vagina comes primarily from internal iliac artery branches, which include the uterine, vaginal, middle rectal, and internal pudendal arteries (Fig. 38-12, p. 801).

INCIDENCE

According to estimates for 2019, approximately 5000 new cases of vaginal cancer will be diagnosed in the United States, and there will be 1430 deaths (Siegel, 2019). The overall incidence is 0.45 cases per 100,000 women but is notably lower in whites (0.42 cases) compared with black and Hispanic women (0.73 and 0.56 cases, respectively) (Watson, 2009). Vaginal cancer rates rise with age and peak among women aged ≥80 years. The median age at diagnosis is 58 (Watson, 2009). Of histologic forms, squamous cell carcinoma accounts for 70 to 80 percent of all primary vaginal cancer cases (Beller, 2003; Ghia, 2011).

SQUAMOUS CELL CARCINOMA

Risks

Squamous cell cancer of the vagina arises within its stratified nonkeratinized epithelium (Fig. 32-1). As with other cancers of the lower reproductive tract, human papillomavirus (HPV) has been closely linked with squamous cell vaginal cancer (Chap. 30, p. 655). A systematic review found an HPV prevalence of 65 percent in samples from invasive vaginal cancer, and a 93-percent prevalence in high-grade vaginal dysplasia lesions. HPV 16 was the most common type and was present in 55 percent of vaginal cancer samplings (Smith, 2009). One retrospective study of 31 countries found similar results (Alemany, 2014).

Because of this association with HPV infection, vaginal in situ and invasive squamous cell carcinomas share risk factors similar to those for cervical cancer. Some of these include multiple lifetime sexual partners, early age at first intercourse, and current cigarette smoking. Women with a vulvar or cervical cancer history also are at greater risk. This last association may stem from the field effect of HPV affecting multiple lower genital tract epithelia or may result from direct tumor spread.

Vaginal intraepithelial neoplasia (VaIN) is a precursor to invasive vaginal cancer, and up to 3 percent of patients with

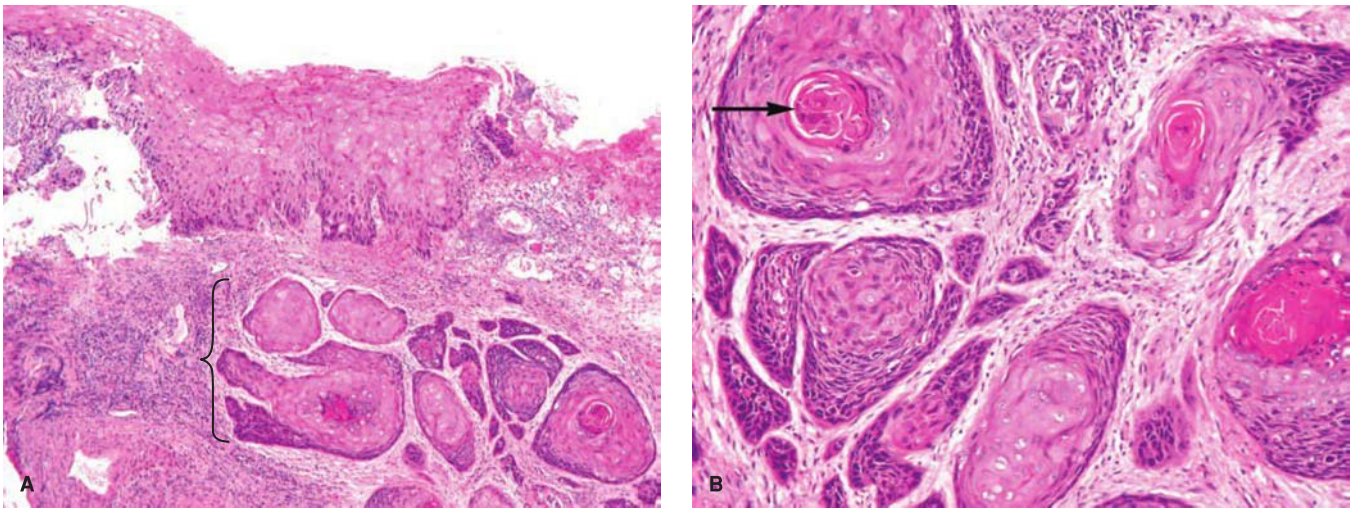

FIGURE 32-1 Sections showing invasive squamous cell carcinoma of the vagina. **A.** Invasive, well-differentiated squamous cell carcinoma of the vagina (*bracket*) invading the subepithelial stroma (×4). **B.** Invasive, well-differentiated squamous cell carcinoma of the vagina (×10). Invasive tumor is composed of irregular nests of malignant squamous cells with keratin pearls (*arrow*) and intercellular bridges. (Reproduced with permission from Dr. Kelley Carrick.)

VaIN will progress to invasive cancer (Ratnavelu, 2013; Zeligs, 2013). Gardasil 9 vaccine is effective against HPV 16 and 18 (Huh, 2017). It is possible that this vaccine will lower future rates of invasive vaginal cancer.

Diagnosis

Vaginal bleeding is the most common complaint associated with vaginal cancer, although pelvic pain and vaginal discharge also may be noted. Less often, lesions involving the anterior vaginal wall may lead to dysuria, hematuria, or urgency. Alternatively, constipation may result from posterior wall masses. Most vaginal cancers develop in the upper third of the vagina.

During pelvic evaluation in all women, the vagina is inspected as the speculum is inserted or removed. If a gross lesion is found, vaginal cancer usually can be diagnosed by punch biopsy in the office. Biopsy may be obtained with Tischler biopsy forceps (Fig. 29-15, p. 637). An Emmett hook, one type of skin hook, may be useful to elevate and stabilize vaginal tissue during biopsy. Monsel paste is applied as needed for hemostasis. If a gross lesion is not detectable, a colposcope can guide directed biopsy. Bimanual examination assists in determining the tumor size, and rectovaginal examination is especially important for posterior wall lesions. Once cancer is diagnosed, no specific laboratory testing other than that used generally for preoperative preparation is required.

[a]Useful for treatment planning but not used to assign FIGO stage.
CT = computed tomography; MR = magnetic resonance.

Staging and Classification

Vaginal cancer staging is completed clinically. This involves physical examination and perhaps cystourethroscopy and/or proctosigmoidoscopy depending on tumor location. If needed, general anesthesia can permit a more detailed pelvic examination for accurate staging. Proctosigmoidoscopy to a depth of at least 15 cm can detect local bowel invasion, whereas cystourethroscopy assists identification of bladder or urethral involvement. Chest radiography aids the search for metastatic disease (Table 32-1 and Table 32-2).

TABLE 32-2. FIGO Staging Classification of Vaginal Cancer

Stage	Characteristics
I	The carcinoma is limited to the vaginal wall
II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall
III	The carcinoma has extended to the pelvic wall
IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

FIGO = International Federation of Gynecology and Obstetrics.

FIGURE 32-2 Computed tomography (CT) scan reveals size and extent of vaginal mass (*arrow*).

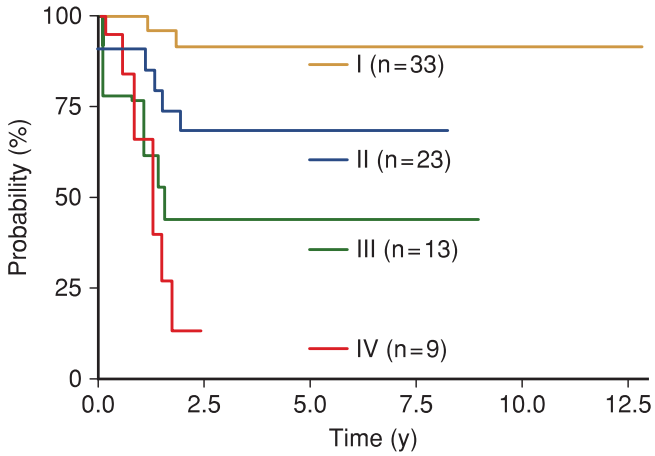

FIGURE 32-4 Disease-specific survival stratified by International Federation of Gynecology and Obstetrics (FIGO) stage. (From Tran, 2007, with permission.)

Computed tomography (CT) scanning, magnetic resonance (MR) imaging, and fluorodeoxyglucose positron emission tomography (FDG-PET) may help treatment planning but are not classically used to determine disease stage. CT scanning can delineate the size and extent of many tumors (Fig. 32-2). However, if the extent of cancer expansion is unclear, MR imaging is the most useful radiologic tool available to visualize the vagina due to its superior soft tissue resolution. FDG-PET can be selected to evaluate lymph node involvement and distant metastases. In one study, FDG-PET was more sensitive than CT for detection of abnormal lymph nodes (Lamoreaux, 2005).

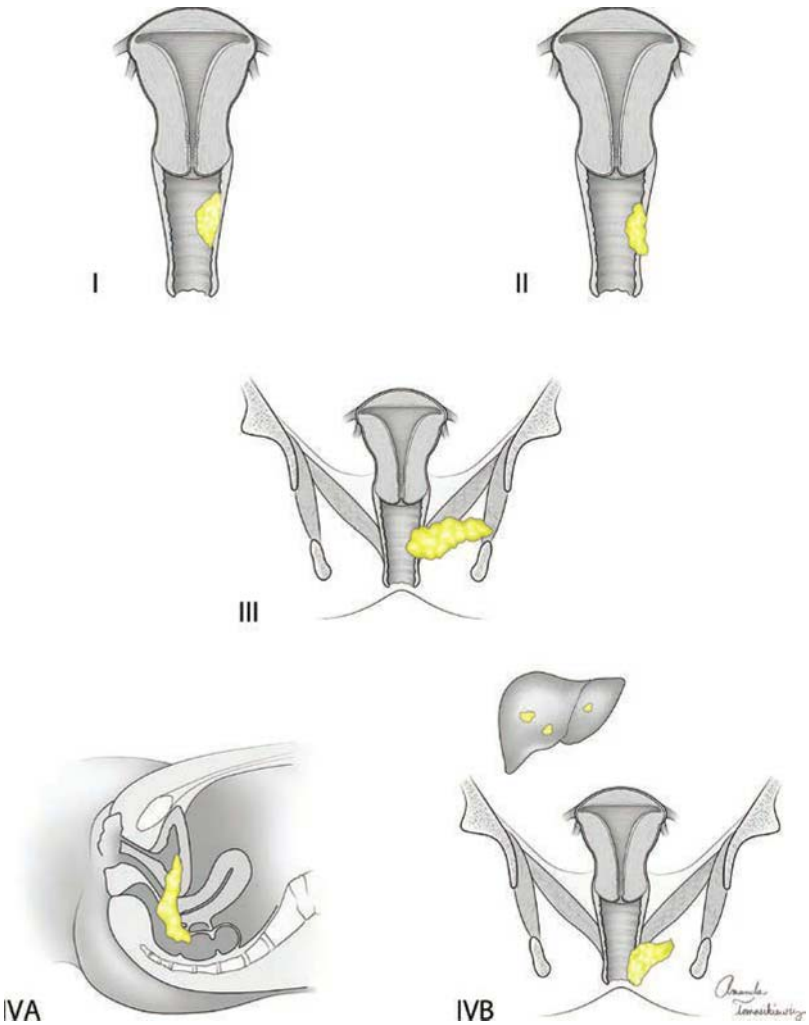

FIGURE 32-3 FIGO (International Federation of Gynecology and Obstetrics) staging of vaginal cancer.

Prognosis

Earlier diagnosis and advances in radiation technology are largely responsible for the improved prognosis of vaginal squamous cell carcinoma. The 5-year survival rate now ranges from 45 to 68 percent for all stages (Ghia, 2011; Hellman, 2006).

The prognosis of vaginal squamous cell carcinoma depends primarily on FIGO stage (Fig. 32-3 and Table 32-2) (Frank, 2005; Rajagopalan, 2014). Other factors associated with poor prognosis include larger tumor size, adenocarcinoma cell type, older age, and tobacco use (Chyle, 1996; Gunderson, 2013; Hellman, 2006). The 5-year disease-specific survival rate is 85 to 92 percent for women with stage I disease, 68 to 78 percent for those with stage II, and 13 to 58 percent for those with stage III or IV (Fig. 32-4) (Frank, 2005; Tran, 2007).

Treatment

Stage I

Because of vaginal cancer's rarity, data are limited to guide evidence-based treatment. Therefore, therapy is individualized and based on factors such as tumor type, stage, location, and size.

For stage I disease, both surgery and radiotherapy are options. However, surgery is preferred for most if negative surgical margins can be achieved. Surgery includes radical vaginectomy, radical hysterectomy (for women with an intact

uterus), and pelvic lymphadenectomy for most tumors located in the upper third of the vaginal vault. A review of the National Cancer Database (NCDB) showed that women with stage I disease treated with surgery alone had a significantly improved 5-year survival rate compared with those treated with radiation (90 percent versus 63 percent) (Creasman, 1998). However, other reports have found no significant difference in disease-free survival rates in women with stage I disease treated with surgery compared with radiation alone (Stock, 1995). Radiotherapy may be delivered by external beam, with or without brachytherapy. Further, brachytherapy alone has been used successfully to treat selected small stage I lesions (Nori, 1983; Perez, 1999; Reddy, 1991).

Stage II

Depending on circumstances and the treating clinician, primary surgery or radiation may be selected for stage II cancers. Stock and colleagues (1995) found a significant survival advantage at 5 years in those with stage II disease treated with surgery compared with those treated with radiation (62 percent versus 53 percent). Review of the NCDB showed that the 5-year survival rate for women with stage II disease treated with surgery alone was 70 percent; with radiotherapy alone, 57 percent; and with a combination of surgery and radiotherapy, 58 percent (Creasman, 1998). However, other researchers have found no survival advantage from surgery compared with radiotherapy in stage II disease (Davis, 1991; Rubin, 1985).

Radiation is generally recommended if negative margins cannot be achieved surgically due to tumor location or size or due to patient comorbidities that preclude surgery. If primary radiation is administered for stage II disease, a combination of external beam radiation and brachytherapy is most common. External beam radiation generally is given first, and depending on tumor response, brachytherapy is tailored to remaining disease. As discussed later, adjuvant chemotherapy is often administered during radiotherapy.

Stage III and IVA

For advanced disease, external beam radiation alone or in combination with brachytherapy is usually administered (Frank, 2005). Concurrent chemotherapy with cisplatin as a radiation adjunct is generally also recommended.

Stage IVB

Metastatic vaginal cancer is not curable, and treatment may include systemic chemotherapy or supportive hospice care. The most common sites of distant spread include liver, lung, and bone. The choice of chemotherapeutic agents is commonly extrapolated from cervical cancer data. For example, bevacizumab (Avastin) was approved by the Food and Drug Administration (FDA) in 2014 as a treatment for metastatic cervical cancer, in combination with paclitaxel and either cisplatin or topotecan. The addition of bevacizumab to these chemotherapy combinations improved overall survival length by approximately 4 months in women with metastatic cervical cancer (Tewari, 2014).

Chemoradiation

The numbers of women with vaginal cancer have been too small for prospective, randomized trials. However, concurrent chemotherapy with cisplatin can be considered to benefit those with locally advanced vaginal cancer because of its proven efficacy for cervical cancer. The characteristics of this agent are described in Chapter 27 (p. 598) and Figure 30-13 (p. 670).

In a Surveillance Epidemiology and End Result (SEER) database analysis of 326 patients with vaginal cancer treated with external beam radiation and/or brachytherapy between 1991 and 2005, a notable rise in sensitizing chemotherapy use was observed after 1999. This coincided with a National Cancer Institute announcement regarding the efficacy of chemoradiation in cervical cancer. Despite this greater use, the authors did not find a survival advantage among those vaginal cancer patients who received chemoradiation compared with radiation alone (Ghia, 2011).

However, data from the NCDB compared women with vaginal cancer treated between 1998 and 2011 with radiation therapy alone or with chemotherapy. Of 8086 women, 49 percent received chemoradiation. The median overall survival rate was 56 months in those patients receiving chemoradiation compared with 41 months for those receiving radiation alone (Rajagopalan, 2014).

Of other agents, a phase II trial, which included 22 cervical cancer patients and three with stage II–IV vaginal cancer, demonstrated a 96-percent response rate for women given weekly cisplatin, radiation, and triapine, a ribonucleotide reductase inhibitor (Kunos, 2013). Larger studies are ongoing in cervical cancer patients.

Chemotherapy

In general, chemotherapy alone is ineffective to treat vaginal cancer, although data are limited. The Gynecologic Oncology Group (GOG) performed a phase II trial evaluating 50-mg/m^2 doses of cisplatin given every 3 weeks for advanced or recurrent vaginal cancer in 26 patients. Only one woman with squamous cell carcinoma achieved a complete response. Five of 16 patients with squamous cell carcinoma had stable disease, and 10 had cancer progression. Based on this trial, single-agent cisplatin is considered to have insignificant activity (Thigpen, 1986).

Radiation Therapy

Radiation to the primary tumor usually involves pelvic external beam radiation coupled with brachytherapy. Concurrent platinum-based chemotherapy may be added in settings described in the last section. Additionally, groin radiation is effective in those with palpable nodal metastases. Moreover, elective irradiation may be delivered to clinically negative inguinal lymph nodes if the distal third of the vagina is involved. In one review, of 100 women who did not receive groin radiation, none developed groin metastases if their disease was confined to the upper two thirds of the vagina. However, 10 percent of patients with lower-third primary tumors and 5 percent with tumors involving the entire length of the vagina developed inguinal node metastases (Perez, 1999).

Surveillance

Treatment failures usually develop within 2 years of primary therapy completion. Patients at low risk for recurrence are usually

examined every 6 months for the first 2 years and then annually. Patients at high risk of recurrence are typically examined every 3 months for the first 2 years, then every 6 months for 5 years (Pingley, 2000; Salani, 2017). After 5 years following treatment, women can be seen annually. A Pap test and pelvic examination with careful attention to the inguinal and scalene nodes are performed. Surveillance with CT or MR imaging is at a clinician's discretion.

Recurrent Disease

Disease recurrence should be confirmed by biopsy if further treatment is planned. Therapeutic options in women with central pelvic recurrence who have had prior pelvic radiation are limited. Pelvic exenteration can be considered if a patient is psychologically and medically fit to undergo radical surgery associated with high morbidity (Chap. 46, p. 1174). It is attempted only in those whose cancer is limited to the central pelvis. Therefore, clinicians are alert to the triad of sciatic pain, leg edema, and hydronephrosis, which suggests pelvic sidewall disease. These women are typically not surgical candidates but can be managed with chemoradiation or with chemotherapy alone for women previously irradiated.

Immunotherapy may be an option for recurrent or metastatic disease after chemotherapy. Pembrolizumab blocks the receptor for *programmed cell death protein 1 (PD-1)* and helps promote a robust immune response against cancer cells. This agent is now FDA-approved for women with recurrent or metastatic cervical cancer after chemotherapy. Potential candidates are those with a *combined positive score* ≥1 (Chung, 2018). This score reflects a ratio of PD-1–carrying cells versus tumor cells and is defined further in Chapter 30 (p. 671).

In general, survival after relapse is poor. In a review of 301 patients, 5-year survival rates were 20 percent for local recurrence and 4 percent for metastatic disease recurrence (Chyle, 1996).

ADENOCARCINOMA

Primary adenocarcinoma of the vagina is rare, making up only 13 percent of all vaginal cancers (Platz, 1995). Histologic types include clear cell, endometrioid, mucinous, and serous carcinomas. These may arise in endometriosis foci, in areas of vaginal adenosis, in periurethral glands, or in wolffian duct remnants. *Adenosis* in the vagina is defined by subepithelial glandular structures lined by mucinous columnar cells that resemble endocervical cells (Sandberg, 1965). These represent residual glands of müllerian origin. Clinically, adenosis appears as red granular spots or patches that do not stain following Lugol solution application. Vaginal adenosis is more common in females exposed to diethylstilbestrol (DES) (Chap. 19, p. 424).

More often, vaginal adenocarcinoma is metastatic disease, typically from the genital tract. Disease is frequently metastatic from the endometrium, although it also may originate from the cervix or ovary (Saitoh, 2005). In addition, adenocarcinoma metastases from the breast, pancreas, kidney, and colon also have been identified in the vagina.

Treatment is similar to that for squamous cell carcinoma. Thus, surgery, radiation, or a combination can be used. Primary vaginal adenocarcinoma in general is more aggressive than squamous cell carcinoma. In one series of 30 patients, it was associated with local and metastatic relapse rates that were more than double those for squamous cell carcinoma (Chyle, 1996).

Clear Cell Adenocarcinoma

Of primary vaginal adenocarcinomas, the clear cell type is most closely associated with DES exposure, described in Chapter 19 (p. 424). In 1971, clear cell adenocarcinoma of the vagina was linked to in utero DES exposure. An estimated 1 to 4 million women used this synthetic estrogen, and approximately 0.01 percent of females exposed in utero developed vaginal clear cell adenocarcinoma (Melnick, 1987). Most DES-exposed patients with vaginal cancer were born between 1951 and 1956, when the drug was prescribed most frequently. The rate of clear cell carcinoma peaked at age 19 for women exposed to DES, with a second peak at age 42 (Huo, 2017).

However, in the Netherlands, a bimodal distribution of vaginal clear cell carcinoma has been observed—the first peak occurring with a mean age of 26 years and the second at 71 years. The younger group had all been exposed in utero to DES, whereas the older group, born before 1947, had not been exposed (Hanselaar, 1997). It remains to be seen if the incidence of vaginal clear cell carcinoma will rise as the DES-exposed population ages.

Treatment is similar to that for squamous cell carcinoma of the vagina. For stage I vaginal clear cell adenocarcinoma, the 5-year survival rate for 219 patients was 92 percent and was equivalent regardless of therapy mode (Senekjian, 1987). With stage II disease, the reported 5-year survival for 76 patients was 83 percent (Senekjian, 1988). A smaller study from MD Anderson shows worse 5-year overall survival rate (34 versus 58 percent) for women with primary adenocarcinoma of the vagina not associated with DES exposure compared with squamous cell carcinoma of the vagina. Five-year survival rates for non-DES-associated vaginal adenocarcinoma were 80 percent for stage I disease, 34 percent for stage II, 26 percent for stage III, and no survivors with stage IV disease (Frank, 2007).

MESENCHYMAL TUMORS

Embryonal Rhabdomyosarcoma

This is the most common malignancy of the vagina in infants and children, and most embryonal rhabdomyosarcomas are the sarcoma botryoides subtype. This rare tumor develops almost exclusively in girls younger than 5 years, although vaginal and cervical sarcoma botryoides have been reported in female adolescents (Copeland, 1985). In infants and children, sarcoma botryoides usually involves the vagina; in reproductive-aged women, the cervix; and after menopause, the uterus. The gross specimen can exhibit multiple polyp-like structures or can be a solitary growth with a nodular, cystic, or pedunculated appearance (Fig. 32-5) (Hilgers, 1970). Although this distinctive appearance may guide diagnosis, the classic histologic finding of this tumor is the rhabdomyoblast. Typical complaints include bleeding or a vaginal mass.

Embryonal rhabdomyosarcomas have a poor prognosis, but sarcoma botryoides is the easiest to treat and has the best

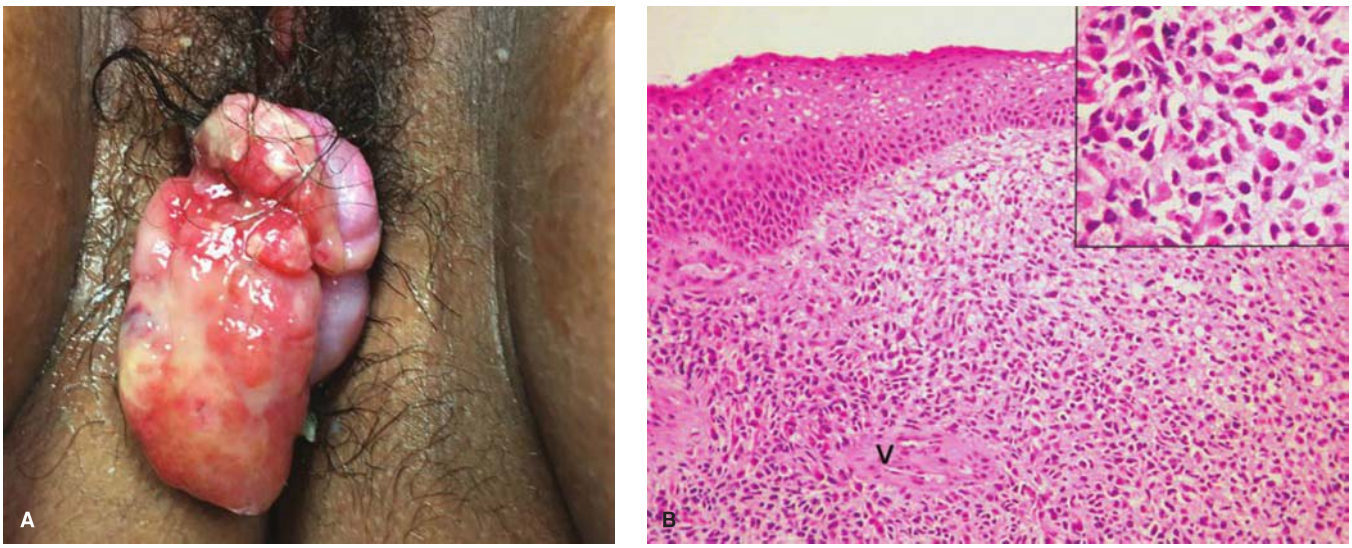

FIGURE 32-5 A. Sarcoma botryoides protruding through the vaginal introitus. (Reproduced with permission from Dr. Ellen Wilson.) **B.** Embryonal rhabdomyosarcoma (×10). Tumor cells lie within a fibromyxoid stroma beneath the vaginal epithelium and cluster around blood vessels (*V*). Inset (×40): Some tumor cells have little discernible cytoplasm, whereas others have a round or strap-like shape and brightly eosinophilic cytoplasm consistent with rhabdomyoblastic differentiation. This example has abundant rhabdomyoblasts. (Reproduced with permission from Dr. Kelley Carrick.)

chance of cure. It may be that its superficial location allows earlier detection. Childhood sarcoma botryoides treatment has dramatically changed. It has gradually shifted away from radical pelvic exenteration surgery and toward primary chemotherapy plus radiation or adjuvant conservative surgery to excise residual tumor (Andrassy, 1995, 1999; Hays, 1985; Pommert, 2017).

Leiomyosarcoma

This is the most common type of vaginal sarcoma in adults. However, it makes up no more than 1 percent of vaginal malignancies, and less than 150 cases have been reported (Khafagy, 2017; Khosla, 2014). The age of affected individuals is broad, but most are older than 40 years (Zaino, 2011). Because of the small number of these tumors, few risk factors have been identified. However, patients previously treated with pelvic radiotherapy for cervical cancer carry a risk.

Affected women most often complain of an asymptomatic vaginal mass, but other symptoms mirror those of their squamous cell counterpart. Any wall of the vagina may be involved, but most tumors develop posteriorly (Ahram, 2006). Microscopically, tumors resemble uterine leiomyosarcoma (Fig. 34-2, p. 724). Tumors spread by local invasion and hematogenous dissemination.

Surgical resection with negative margins is the preferred primary treatment. The benefit of adjuvant radiation is unclear due to a lack of controlled trials. However, some clinicians recommend adjuvant radiation for those with high-grade tumor or local recurrence (Curtin, 1995).

MELANOMA

Primary malignant melanoma in the vagina is rare, accounting for less than 3 percent of all vaginal cancers. In women, only 1.6 percent of melanomas are genital. Of genital sites, the most common is the vulva (70 percent), followed by the vagina (21 percent), and the cervix (9 percent) (Miner, 2004). Using data from the SEER database, the incidence of vaginal melanoma lies between 0.26 and 0.46 per 1 million women per year (Hu, 2010; Weinstock, 1994). From U.S. and Swedish studies, the mean age at diagnosis was 66 years (Ragnarsson-Olding, 1993; Reid, 1989).

Presenting symptoms include vaginal bleeding, discharge, and vaginal mass (Fig. 32-6) (Gupta, 2002; Reid, 1989). Most are located in the distal vagina (Frumovitz, 2010; Xia, 2014). Vaginal melanoma is often detected late, and this may be largely responsible for poor treatment outcomes.

With a reported 5-year survival rate ranging from 10 to 20 percent, the prognosis is among the worst of vaginal malignancies

FIGURE 32-6 Vaginal melanoma of the anterior vaginal wall. Below the mass, a tenaculum can be seen on the uninvolved cervix. (Reproduced with permission from Drs. Siobhan Kehoe and Dustin Manders.)

(Ragnarsson-Olding, 1993; Xia, 2014). Although survival rates are significantly better for those with vaginal lesions measuring <3 cm, FIGO staging of vaginal melanomas does not accurately predict survival (Reid, 1989). Thus, staging criteria specific to melanoma are used. Cutaneous melanomas at other body sites use microstaging systems, including the Chung, the Clark, and the Breslow systems. These employ criteria such depth of invasion, tumor size, and tumor thickness (Chap. 31, p. 686). However, Clark levels are not applicable to vaginal melanoma because the needed microscopic skin landmarks are absent. Therefore, staging is based on tumor thickness, as described by Breslow or Chung.

Treatment is extrapolated from cutaneous melanomas, due to the rarity of vaginal melanoma. Surgery is preferred, when feasible. Although some advocate radical surgery, including exenteration, growing evidence shows that wide local excision has similar survival rates and less morbidity (Buchanan, 1998; Xia, 2014). The recommended clinical surgical margin for a melanoma with a Breslow thickness ≤1 mm is 1 cm; a thickness 1 to 2 mm warrants a 1- to 2-cm margin; and a thickness >2 mm requires a 2-cm margin (National Comprehensive Cancer Network, 2019). One study demonstrated a survival benefit to the wide local excision approach (Frumovitz, 2010). However, because of their size or location and the required margins, many vaginal melanomas are not amenable to this less radical approach.

Melanomas generally are thought to be radioresistant. However, radiotherapy in one series provided local tumor control in women who had surgically unresectable disease (Miner, 2004).

For advanced or metastatic cutaneous melanoma, several targeted biologic agents are available. B-Raf and KIT proteins are involved with directing cell growth, and mutations in their transcribing genes can lead to altered growth. Mutations in the *BRAF* and *KIT* genes are found in some cutaneous and mucosal melanomas, and vaginal melanoma tumors are tested for these mutations (Leitao, 2014). Of mutated genes in vaginal and vulvar melanomas, *BRAF* mutations make up 26 percent, and *KIT* mutations compose 22 percent (Hou, 2017). Options for those with $BRAF^{V600E}$ mutations include combined BRAF and MEK inhibition by vemurafenib plus dabrafenib or by vemurafenib plus cobimetinib (Flaherty, 2012; Larkin, 2014; Long, 2014, 2015; National Comprehensive Cancer Network, 2019). Imatinib may be used for tumors with the *c-KIT* mutation (Carvajal, 2011). Ipilimumab is a monoclonal antibody that promotes T-cell activation, which in turn produces antitumor effects. Its use in melanoma patients improves overall survival rates (Hodi, 2010). Last, both PD-1 and its ligand, which is *programmed cell death ligand 1 (PD-L1)*, also are frequently expressed in vulvar and vaginal melanoma: 75 and 56 percent, respectively. Nivolumab and pembrolizumab, which are monoclonal antibodies against PD-1, are options for metastatic or unresectable cutaneous melanoma (Hamid, 2018).

In the United States, endometrial cancer is the most common gynecologic malignancy. Risk factors include obesity and advancing age. As these factors are now more prevalent, the incidence of endometrial cancer continues to rise. Fortunately, patients usually seek medical attention early due to vaginal bleeding, and endometrial biopsy leads quickly to diagnosis. The cornerstone of treatment is hysterectomy with bilateral salpingo-oophorectomy (BSO) and surgical staging that includes lymph node assessment for most women. Of affected women, 67 percent will have stage I disease that is potentially curable by surgery alone, although high-risk stage I patients often receive adjuvant therapy (Siegel, 2019). The 21 percent of patients with regional disease and 8 percent with distant disease typically require multimodality treatment that includes some combination of surgery, chemotherapy, and radiotherapy.

EPIDEMIOLOGY AND RISK FACTORS

From the Surveillance, Epidemiology, and End Results (SEER) Program (2018) database, women in the United States have a 3-percent lifetime risk of developing endometrial cancer. In 2019, an estimated 61,880 new cases and 12,160 associated deaths are expected (Siegel, 2019). Most patients are diagnosed early and subsequently cured. As a result, endometrial cancer is the fourth leading cause of cancer, but only the sixth leading cause of cancer deaths among women.

Endometrial adenocarcinomas are categorized as type I or type II based on histology. Type I, that is, endometrioid type, makes up 80 to 90 percent of all cases (Felix, 2010). The other 10 to 20 percent are type II cancers, namely, the non-endometrioid histologic types that include serous and clear cell adenocarcinomas and carcinosarcoma. Risk factors for developing endometrial cancer are numerous (Table 33-1). Risks specifically for type I cancers are associated with an excess-estrogen environment.

Of these, *obesity* is the most common cause of endogenous overproduction of estrogen. Excessive adipose tissue increases peripheral aromatization of androstenedione to estrone. In premenopausal women, elevated estrone levels trigger abnormal feedback in the hypothalamic-pituitary-ovarian axis. The clinical result is oligo- or anovulation. In the absence of ovulation, the endometrium is exposed to virtually continuous estrogen stimulation without subsequent progestational effect and without menstrual shedding.

Unopposed estrogen therapy is the next most important potential inciting factor. Fortunately, the malignant potential of continuously administered estrogen was recognized decades ago

TABLE 33-1. Factors Affecting Endometrial Cancer Risk

Raise risk
Obesity
Polycystic ovarian syndrome
Long-term, high-dose unopposed menopausal estrogens
Early age of menarche
Late age of natural menopause
Infertility
Nulliparity
Menstrual irregularities
North America or northern Europe residence
Higher education or income level
White race
Older age
Tamoxifen, high cumulative doses
DM, CHTN, or gallbladder disease
Lower risk
Long-term COC use
Cigarette smoking

CHTN = chronic hypertension; COC = combination oral contraceptive; DM = diabetes mellitus.

(Smith, 1975). Currently, it is rare to encounter a woman with a uterus who has taken unopposed estrogen for years. Instead, combined estrogen plus progestin hormonal replacement therapy (HRT) is routinely prescribed for postmenopausal women with a uterus to reduce estrogen-related endometrial cancer risk (Strom, 2006).

Menstrual and reproductive influences are commonly associated with endometrial cancer. For example, early age at menarche or late age of menopause are both associated with higher risk (Wernli, 2006). Classically, women with polycystic ovarian syndrome (PCOS) are anovulatory and thus also have an increased risk of developing this cancer (Fearnley, 2010; Pillay, 2006).

Older age is linked with endometrial cancer development. The average age at diagnosis is the early 60s, and overall, approximately 80 percent of these cancers are diagnosed in postmenopausal women older than 55 years (Madison, 2004; Schottenfeld, 1995). From the SEER database (2018), approximately 7 percent of endometrial cancers develop in patients younger than 45 years. Of note, Nevadunsky and associates (2014) found that the age at diagnosis of endometrioid cancer decreased linearly with increasing body mass index (BMI).

Family history is another risk for endometrial cancer. Endometrial cancer is the most common extracolonic manifestation of Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) (Hemminki, 2005). This autosomal-dominant syndrome results primarily from mutations in the mismatch repair genes *MLH1, MSH2, MSH6,* and *PMS2* (Bansal, 2009). Gene mutation prevents repair of base mismatches, which are commonly produced during DNA replication. Inactivity of this DNA repair system leads to mutations that can promote carcinogenesis. Mutation carriers have a risk of developing endometrial cancer that ranges from 40 to 60 percent. Among affected women, endometrial cancer often develops at a young age, and the risk for this cancer actually exceeds that for colorectal cancer (Aarnio, 1999; Delin, 2004). Of all endometrial cancer cases, 2.3 percent are attributable to Lynch syndrome, and these cases develop more than 10 years earlier than sporadic endometrial cancer (Resnick, 2009).

Tamoxifen causes a two- to threefold higher risk of developing endometrial cancer by its modest "unopposed" estrogenic effect on the endometrium (Chap. 27, p. 598). The increased risk of endometrial cancer affects postmenopausal women almost exclusively, and cancer rates rise linearly with the duration and cumulative dose of tamoxifen therapy (Fisher, 1998; van Leeuwen, 1994). Accordingly, women taking tamoxifen are counseled regarding this endometrial risk and should report vaginal spotting, bleeding, or discharge. That said, unless a tamoxifen-treated patient has such symptoms, routine endometrial surveillance does not improve early detection rates (American College of Obstetricians and Gynecologists, 2019c).

Coexisting medical conditions such as diabetes mellitus, hypertension, and gallbladder disease are more commonly associated with endometrial cancer (Morimoto, 2006; Soliman, 2005). In general, these are frequent sequelae of obesity and an excess estrogen environment and are considered epiphenomena rather than causal.

In contrast, *combination oral contraceptive* (COC) use for at least 1 year confers as much as a 30- to 50-percent reduced endometrial cancer risk. Risk reduction extends for 10 to 20 years (Dossus, 2010; Stanford, 1993). This most likely derives from a chemopreventive effect on the endometrium provided by the progestin component (Maxwell, 2006). Logically, progesterone intrauterine devices (IUDs) also confer long-term endometrial cancer protection (Tao, 2006). Of interest, similar protective effects are seen with inert and copper IUD types (Felix, 2015).

Smokers have a lower risk of endometrial cancer. The biologic mechanism is multifactorial but in part involves lower circulating estrogen levels from weight reduction, earlier age at menopause, and altered hormonal metabolism. Both current and past smoking have a long-lasting influence (Viswanathan, 2005).

ENDOMETRIAL HYPERPLASIA

Most endometrial cancers arise following progression of histologically distinguishable hyperplastic lesions. In fact, endometrial hyperplasia is the only known direct precursor of invasive disease. Endometrial hyperplasia is defined as endometrial thickening with proliferation of irregularly sized and shaped glands and an increased gland-to-stroma ratio (Fig. 33-1) (Ellenson, 2011b). In the absence of such thickening, lesions are best designated as *disorderly proliferative endometrium* or *focal glandular crowding*.

Classification

Endometrial hyperplasia represents a continuum of histopathologic findings. The classification system used by the World Health Organization (WHO) and International Society of Gynecological Pathologists designates two different types with varying malignant potential (Kurman, 1985, 2014). *Hyperplasia without atypia* is characterized by exaggerated endometrial gland proliferation and an increased gland-to-stroma ratio compared with normal proliferative endometrium, but without significant cytologic atypia (see Fig. 33-1). Most importantly, hyperplasias are additionally labeled as atypical if they demonstrate nuclear atypia of the endometrial gland cells. *Atypical endometrial hyperplasias* are clearly associated with the subsequent development of adenocarcinoma (Table 33-2).

Although endometrial hyperplasias are formally classified in these two different groups, they tend to be morphologically

TABLE 33-2. World Health Organization Classification of Endometrial Hyperplasia

Types	Progressing to Cancer (%)
Simple hyperplasia	1
Complex hyperplasia	3
Simple atypical hyperplasia	8
Complex atypical hyperplasia	29

Data from Kurman, 1985.

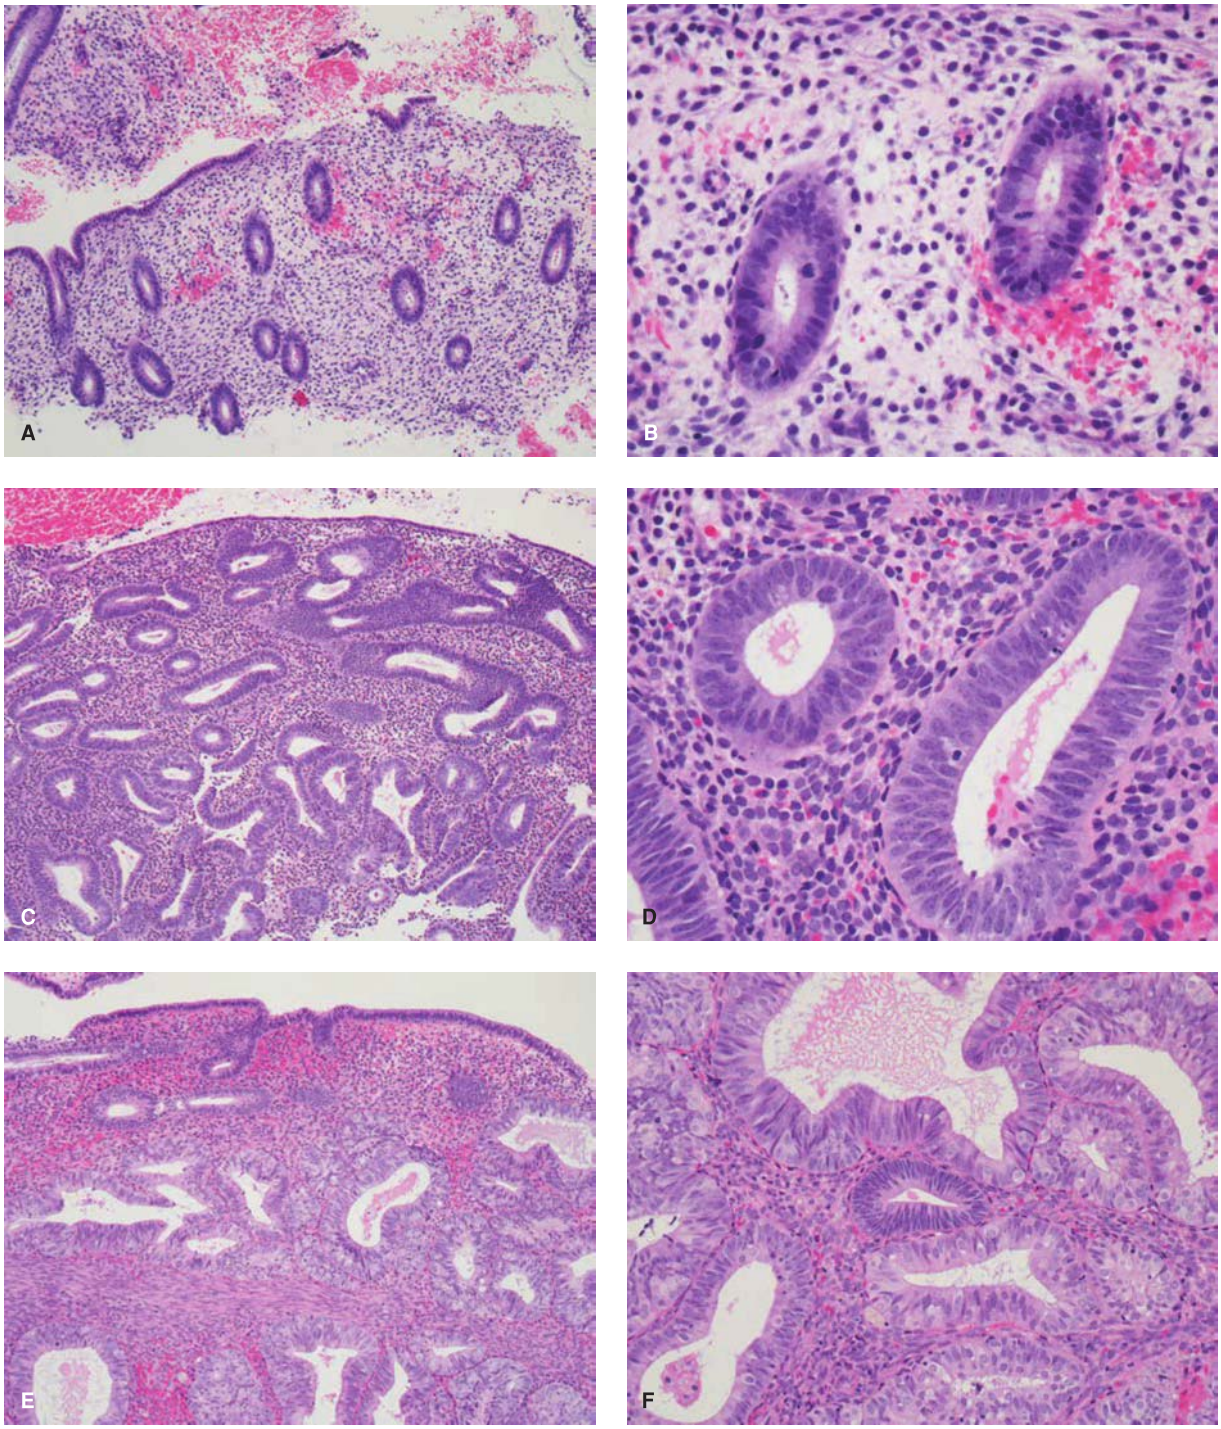

FIGURE 33-1 A. Normal proliferative endometrium shows regularly spaced, tubular endometrial glands. **B.** Normal proliferative endometrial glands have columnar lining cells with relatively bland, ovoid, mitotically active nuclei. **C.** In hyperplasia without atypia, the endometrial glands are crowded, and some have irregular shapes. **D.** In hyperplasia without atypia, glands are crowded but devoid of significant cytologic atypia. The nuclear stratification, mitotic activity, and apoptosis seen in these glands are features of normal proliferative endometrium. **E.** Hyperplasia with atypia/endometrioid intraepithelial neoplasia (EIN). The endometrial glands are crowded and complex and have nuclear atypia. **F.** Atypical hyperplasia/EIN. The atypical glandular epithelium has a tubal character in this particular example (note scattered ciliated cells). This contrasts with the single normal gland in the photograph's center (Reproduced with permission from Dr. Kelley Carrick.)

heterogeneous, both within and between individual patients. This histologic diversity explains why only a small number of conserved features are useful as diagnostic criteria. As a result, reproducible scoring of cytologic atypia is often challenging, particularly with a small amount of tissue from a biopsy sample.

Endometrial intraepithelial neoplasia (EIN) is a term introduced to more accurately distinguish the two very different clinical categories of hyperplasia. These are: (1) normal polyclonal endometria diffusely responding to an abnormal hormonal environment and (2) intrinsically proliferative monoclonal lesions

that arise focally and confer an elevated risk of adenocarcinoma (Mutter, 2000). This nomenclature emphasizes the malignant potential of endometrial precancers and is in keeping with similar precedents in the cervix (CIN [cervical intraepithelial neoplasia]), vagina (VaIN), and vulva (VIN) (Chap. 29, p. 620).

Using this system, anovulatory or prolonged estrogen-exposed endometria without atypia are generally designated as *endometrial hyperplasias*. In contrast, EIN is used to describe all endometria delineated as premalignant by a combination of three morphometric features. The qualities reflect glandular volume, architectural complexity, and cytologic abnormality. The EIN classification system is a more accurate and reproducible way to predict progression to cancer and is recognized by the American College of Obstetricians and Gynecologists and Society of Gynecologic Oncology (2017a). However, it has not been universally implemented (Baak, 2005; Hecht, 2005).

Clinical Features and Diagnosis

The risks for developing endometrial hyperplasia generally mirror those for invasive carcinoma (Anastasiadis, 2000; Ricci, 2002). Two thirds of women present with postmenopausal bleeding (Horn, 2004). However, premenopausal women with abnormal uterine bleeding (AUB) are also evaluated as described in Chapter 8 (p. 182).

As hyperplasia is a histologic diagnosis, a Pipelle office endometrial biopsy (EMB) or outpatient dilation and curettage (D & C) are suitable choices for endometrial sampling. The American College of Obstetricians and Gynecologists (2016) recommends such a sample for women older than 45 years with AUB. EMB is also considered for those younger than 45 with chronic excess estrogen exposure (exogenous or endogenous), failed medical management, and persistent AUB.

In those with AUB, transvaginal sonography to measure endometrial thickness can also predict endometrial hyperplasia (Granberg, 1991; Jacobs, 2011). This option can be offered as an initial evaluation only to women with postmenopausal bleeding for whom no further evaluation would be needed if a thin stripe is found. For these women, endometrial stripe thickness measurements ≤4 mm are associated with bleeding that is attributed to endometrial atrophy (American College of Obstetricians and Gynecologists, 2018b). Postmenopausal women with a thicker endometrium warrant biopsy. Sonography may also identify abnormal echostructural changes in the endometrium. Cystic endometrial changes suggest polyps, homogeneously thickened endometrium may indicate hyperplasia, and a heterogeneous structural pattern is suspicious for malignancy (Figs. 33-2 and 33-3). However, these sonographic findings show great overlap and cannot be used alone.

Endometrial thickness >4 mm may be identified in postmenopausal women undergoing sonographic evaluation for reasons unrelated to postmenopausal bleeding. The positive predictive value of an "abnormal" endometrial thickness in asymptomatic women would be expected to be low, because the disease prevalence in asymptomatic patients is low. It is therefore reasonable to use a higher threshold value for these patients. The Society of Obstetrics and Gynecology of Canada suggests 11 mm as the threshold in asymptomatic women (Wolfman, 2010). This comports with a decision analysis by Smith-Bindman and colleagues (2004).

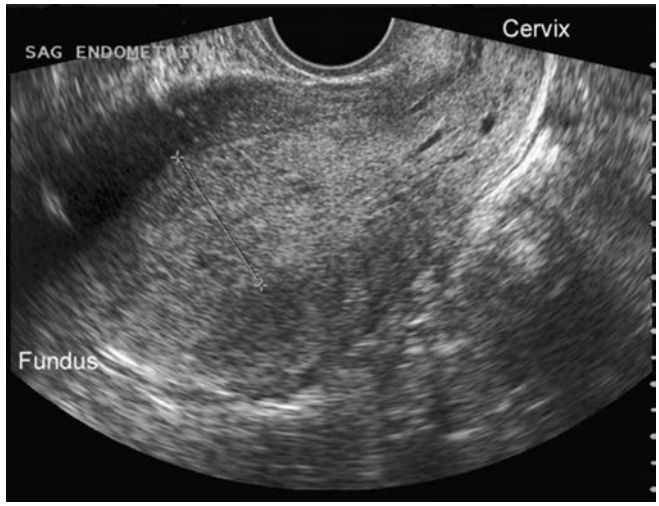

FIGURE 33-2 Transvaginal sonographic image of a uterus. In this sagittal view, the markedly thickened endometrium, which is measured by the calipers, suggests endometrial hyperplasia. (Reproduced with permission from Dr. Elysia Moschos.)

For premenopausal women, transvaginal sonography is often performed to exclude structural sources of abnormal bleeding. Similarly, researchers have attempted to create endometrial thickness guidelines. However, endometrial thicknesses can vary considerably among premenopausal women during normal menstrual cycling. From studies, suggested evidence-based abnormal thresholds range from >4 mm to >16 mm (Breitkopf, 2004; Goldstein, 1997; Shi, 2008). Thus, consensus for an endometrial thickness threshold has not been established for this group. Thus, to exclude endometrial cancer, endometrial biopsy is preferred to sonography for high-risk premenopausal women with AUB.

Of other tools, hysteroscopy is more sensitive for focal endometrial lesions. However, hyperplastic endometrium is grossly indistinct, and thus hysteroscopy has poor sensitivity for this diagnosis (Ben Yehuda, 1998; Garuti, 2006).

FIGURE 33-3 Transvaginal sagittal image of the endometrium from a 38-year-old woman with chronic oligomenorrhea. The abnormal endometrium is thickened, echogenic, and heterogeneous in echotexture and contains tiny cystic foci. Biopsy revealed grade 1 endometrioid adenocarcinoma, which was confirmed at surgery. (Reproduced with permission from Dr. Elysia Moschos.)

Treatment

Management of women with endometrial hyperplasia mainly depends on a patient's age, comorbid risks for surgery, desire for fertility, and specific histologic features such as cytologic atypia. Hysterectomy is the most definitive treatment. Hormonal therapy is another option and includes oral or injectable progestins or the progestin (levonorgestrel-releasing) IUD.

With hyperplasia, diagnosis at times may be inconsistent due to interobserver variability among pathologists. Moreover, predicting the stability of individual lesions can be difficult. Specifically, several studies have documented low reproducibility for WHO classifications of endometrial hyperplasia (Allison, 2008; Sherman, 2008; Zaino, 2006). In addition, there is no way to anticipate which types will involute with progestin therapy. However, as long as an endometrial sample is representative and a provider has no reason to suspect a coexisting invasive carcinoma, the decision to treat endometrial hyperplasia through hormonal or surgical means relies on clinical judgment.

Nonatypical Endometrial Hyperplasia

Premenopausal Women. Nonatypical lesions may spontaneous regress without therapy. However, progestins are generally used to address the underlying etiology, that is, chronic anovulation and excess estrogen (Terakawa, 1997). Premenopausal women with nonatypical endometrial hyperplasia typically require a 3- to 6-month course of low-dose progestin therapy. Cyclic medroxyprogesterone acetate (MPA) (Provera) given orally for 12 to 14 days each month at a dose of 10 to 20 mg daily is commonly used. Continuous daily dosing with MPA 10 mg is suitable and may be more effective than cyclic administration in reversing hyperplastic changes. Another frequently used option is COC pills for those without contraindications. The levonorgestrel-releasing IUD also is effective (Gallos, 2010; Ørbo, 2014; Scarselli, 2011).

Generally, a posttreatment EMB is performed to document regression. In those with an IUD, EMB can be performed without device removal. After regression, a key point is to continue endometrial protection. Thus, once hyperplastic changes resolve, patients are continued on progestins and observed until menopause. Additional endometrial sampling is required for new bleeding.

Postmenopausal Women. Postmenopausal women with nonatypical endometrial hyperplasia may also be treated with low-dose oral cyclic MPA or a continuous 10-mg daily regimen. Importantly, in older women, providers should be confident that the sample obtained is adequate to exclude cytologic atypia. D & C may be indicated at times, especially if the tissue from Pipelle sampling is scant or if recurrent bleeding is noted.

Affected postmenopausal patients who have a contraindication to progestin therapy or who cannot tolerate the therapy can be expectantly managed. Complex hyperplasia without atypia is usually treated chronically with progestins. Office endometrial biopsy is recommended every 3 to 6 months until lesion resolution is achieved.

Response to Progestins. In cases of endometrial hyperplasia without atypia, the risk of progression to endometrial cancer is low and only 1 to 3 percent. The overall clinical and pathologic regression rates to progestin therapy range from 70 to 80 percent for nonatypical endometrial hyperplasia (Rattanachaiyanont, 2005; Reed, 2009). Patients with persistent disease on repeated biopsy may be switched to a higher-dose regimen such as MPA 40 to 100 mg orally daily. Also, megestrol acetate (Megace), 160 mg daily or 80 mg twice daily, is suitable. It can be increased even up to 160 mg twice daily if no regression is initially achieved. Again, a clinician must confirm that hormonal ablation has occurred by resampling the endometrium after a suitable therapeutic interval, usually 3 to 6 months. Hysterectomy may also be considered for lesions that are refractory to medical management.

If surgery is selected, a minimally invasive surgery (MIS) approach is considered, and options are laparoscopic, robotic, or vaginal hysterectomy. In cases in which hyperplasia has been proven or is suspected, the uterus is removed in toto and without morcellation, which might disseminate disease. Because the lesion may extend into the lower uterine segment or upper endocervix, supracervical hysterectomy is not appropriate for women undergoing hysterectomy for treatment of endometrial hyperplasia.

Atypical Endometrial Hyperplasia

Hysterectomy is the preferred treatment for women with atypical endometrial hyperplasia because the risk of progression to cancer over time approximates 29 percent. The rate of finding concurrent invasive malignancy coexistent with the atypical hyperplasia also is significant (Horn, 2004; Trimble, 2006). In postmenopausal women, a hysterectomy with removal of both tubes and ovaries is recommended.

In premenopausal women who have completed childbearing, hysterectomy is performed for hyperplasia. Risk-reducing salpingectomy is encouraged to potentially lower cancer risk that arises from the fallopian tubes (American College of Obstetricians and Gynecologists, 2019b). For premenopausal women, removal of the ovaries is optional. The deciding factors mirror those for women contemplating BSO for other benign indications and are outlined fully in Chapter 43 (p. 957).

Premenopausal women who strongly wish to preserve fertility can be treated with progestins (Trimble, 2012). High-dose progestin therapy, megestrol acetate 80 mg orally twice daily, is an option for motivated patients who will be compliant with surveillance (Randall, 1997). The IUD that releases 20 μg of intrauterine levonorgestrel daily (Mirena, Liletta) also is suitable (Ørbo, 2014). Poor surgical candidates may also warrant an attempt at hormonal ablation with progestins. Resolution of the hyperplasia must be confirmed by serial endometrial biopsies every 3 months until response is documented. Otherwise, hysterectomy is recommended. Following hyperplasia resolution, surveillance and progestins continue long-term due to the potential for eventual progression to carcinoma (Rubatt, 2005). Once fertility is complete, hysterectomy is again recommended.

The Gynecologic Oncology Group (GOG) performed a prospective cohort study of 289 patients who had a diagnosis of atypical endometrial hyperplasia. Participants underwent hysterectomy within 3 months of their biopsy, and 43 percent were found to have a concurrent endometrial carcinoma (Trimble, 2006). Suh-Burgmann and associates (2009) found a similarly high number of 48 percent. Results demonstrate the difficulty

TABLE 33-3. Type I and II Endometrial Carcinoma: Distinguishing Features

in attaining an accurate diagnosis before hysterectomy and the potential risks of conservative hormonal treatment. The high risk of coexistent endometrial cancer has prompted some surgeons to perform frozen section analysis of the endometrium at the time of hysterectomy in these cases. Surgical staging then proceeds if carcinoma is found.

ENDOMETRIAL CANCER

Pathogenesis

Endometrial cancer is a biologically diverse group of neoplasms characterized by a dualistic model of pathogenesis. As noted, type I endometrioid adenocarcinomas constitute most cases. They are estrogen-dependent, low grade, and derived from atypical endometrial hyperplasia. In contrast, type II cancers are serous, carcinosarcoma, or clear cell histology; have no precursor lesion; and portend a more aggressive clinical course (Table 33-3).

From molecular studies, endometrial cancers can be broadly categorized based on genomic alterations in the tumors. The four groupings are POLE-ultramutated; microsatellite instability-high (MSI-H); copy number–low; and copy number–high (Kandoth, 2013). These categories are associated with distinct prognoses and clinical features and may help predict treatment response.

POLE-ultramutated tumors harbor mutations in the *POLE* gene, which encodes the DNA polymerase epsilon catalytic subunit. Although their associated histology is usually high-grade endometrioid or clear cell, they carry a favorable prognosis. They are heavily infiltrated with *tumor infiltrating lymphocytes (TILs)* and overexpress *programmed death 1 (PD-1)* (Bellone, 2017). The latter is an important regulator of immune response and illustrated in Figure 27-7 (p. 601). These observations suggest that tumor immunology may play a role in their good prognosis.

Copy number–high tumors are characterized by mutations in *TP53,* which encodes the tumor suppressor protein p53. These tumors have a poor prognosis, and all serous and some high-grade endometrioid and clear cell carcinomas fall into this category.

Copy number–low tumors are generally low-grade and endometrioid type. These do not harbor *TP53* mutations but have frequent mutations in *PTEN*, which also codes for a tumor suppressor protein, and other genes. These tumors have an intermediate prognosis.

MSI-H tumors have defects in genes responsible for the repair of single base-pair mismatches. Damaged base pairs persist and lead to instability in short tandem DNA sequences, called *microsatellites*, and create genomic instability in general. In tumors, the MSI-H phenotype can be detected by direct microsatellite DNA sequence testing. Alternatively, indirect immunohistochemistry staining can test for the four proteins expressed by the mismatch repair (MMR) genes *MLH1*, *MSH2*, *MSH6*, and *PMS2.*

Although Lynch syndrome–associated endometrial cancers are MSI-H, most MSI-H tumors endometrial cancers are sporadic. MSI-H endometrial cancers have a favorable prognosis (Haruma, 2018). The MSI-H phenotype, in endometrial cancers and also other cancers, responds well to PD-1–directed immunotherapy (Ott, 2017).

Prevention

Education can be effective prevention, as many endometrial cancer risks are alterable. Women with PCOS may benefit from weight loss and chronic progestin supplementation (Chap. 18, p. 400). Assessing and managing obesity may also lower risks (Chap. 1, p. 12). In a recent systematic review of five retrospective studies, patients who underwent bariatric surgery had a 68-percent endometrial cancer risk reduction compared with women who did not have this surgery (Winder, 2018).

Even for women at increased risk, routine screening of hyperplasia or endometrial cancer is not advocated. Instead, at the onset of menopause, women are counseled on the risks and symptoms of endometrial cancer and strongly encouraged to report unexpected bleeding or spotting to their provider. One screening exception is the woman with Lynch syndrome. For these individuals, EMB is recommended every 1 to 2 years beginning at age 30 to 35 years (American College of Obstetricians and Gynecologists, 2019a; Smith, 2019).

Genetic testing criteria have been published to identify the individual with Lynch syndrome (Table 33-4) (Lancaster, 2015).

TABLE 33-4. Lynch Syndrome Genetic Screening Recommendations

Patients with endometrial or colorectal cancer and tumor evidence of: Microsatellite instability or DNA mismatch repair protein loss (see Fig. 33-4)
First-degree relative with endometrial or colorectal cancer who was diagnosed: Before age 60 years or Is at risk for Lynch syndrome based on personal and medical history
First- or second-degree relative with a known DNA mismatch repair gene mutation

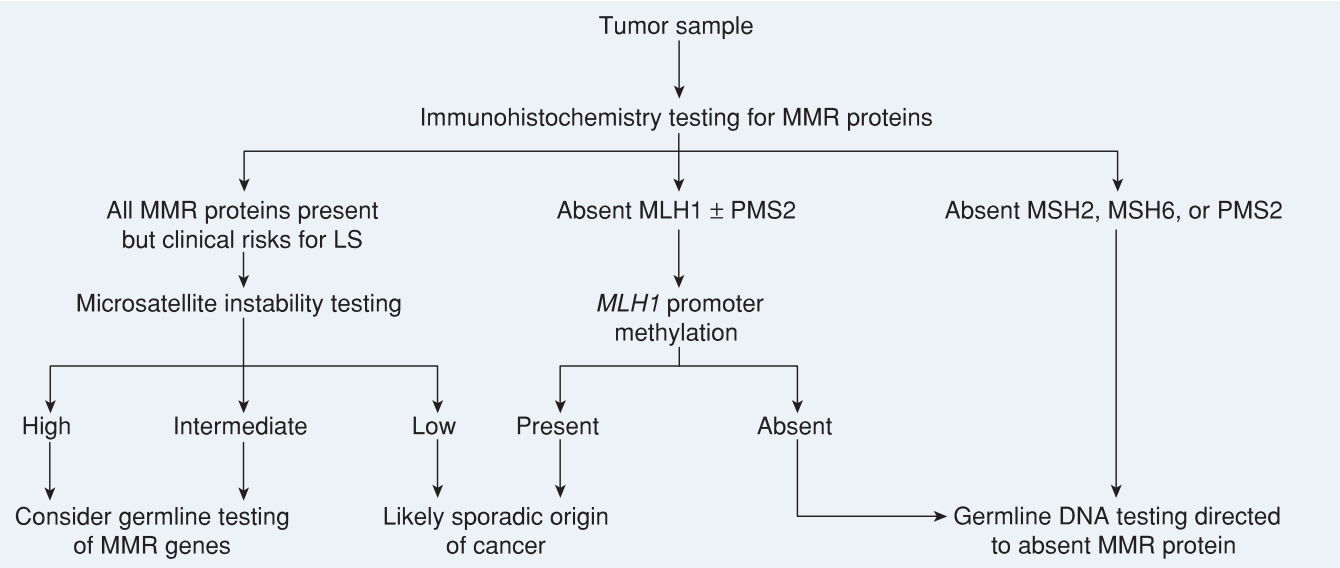

FIGURE 33-4 This algorithm begins with tumor testing for Lynch syndrome–associated proteins and genes. Immunohistochemistry staining of histologic slides is directed to the mismatch repair (MMR) proteins of interest. Right: If MSH2, MSH6, or PMS2 proteins are absent, then germline DNA testing is recommended. Center: If the MLH1 protein is absent, testing evaluates the promoter region of the *MLH1* gene. Silencing of *MLH1* by methylation reflects a sporadic, noninherited origin of the cancer. Left: If all MMR proteins are present but Lynch syndrome (LS) is still suspected, the degree of microsatellite instability in known DNA regions is evaluated. The degree of instability correlates with the risk for Lynch syndrome.

Lynch syndrome cancers include colon, endometrium, small bowel, renal pelvis and ureter, and ovary, among others (Vasen, 1999). Referral for genetic counseling based on family history can further clarify which patients may benefit from specific germline testing. For patients with endometrioid endometrial cancer, Lynch syndrome screening is performed by immunohistochemistry staining of the tumor to search for the four most important Lynch syndrome proteins, described in the last section. Intact expression of all four proteins is associated with a low risk of Lynch syndrome. These women can be counseled that formal genetic testing is unnecessary in most cases (Provenzale, 2018). For patients who have negative screening results but who are still suspected of having Lynch syndrome based on family history, further testing for microsatellite instability may be performed. The combination of intact protein expression and lack of microsatellite instability predicts a very low risk of Lynch syndrome. In these cases, formal genetic testing may be deferred, unless clinical suspicion is high. Some advocate screening all patients with endometrioid endometrial cancer. Other suggest a more selective approach, for example, screening all patients <65 years. One Lynch syndrome screening algorithm is Figure 33-4.

Because women with Lynch syndrome have such a high lifetime risk of developing endometrial cancer (40 to 60 percent), prophylactic hysterectomy is recommended once affected women reach the early to mid 40s and have completed childbearing. In a cohort of 315 Lynch syndrome patients, Schmeler and coworkers (2006) confirmed the benefit of this approach by reporting a 100-percent endometrial cancer risk reduction. In general, BSO also is performed due to the 9- to 12-percent lifetime risk of ovarian cancer. Prior to hysterectomy, colon cancer screening with colonoscopy should be up to date (American College of Obstetrician and Gynecologists, 2019a).

Diagnosis

Signs and Symptoms

Early diagnosis of endometrial cancer is almost entirely dependent on the prompt recognition and evaluation of irregular vaginal bleeding. In premenopausal women, a clinician must maintain a high index of suspicion for a history of prolonged, heavy menstruation or intermenstrual spotting, because many other benign disorders give rise to similar symptoms (Table 8-2, p. 182). Postmenopausal bleeding is particularly worrisome and carries a 5- to 10-percent likelihood of diagnosing endometrial carcinoma (Clarke, 2018; van Hanegem, 2017). Abnormal vaginal discharge may be another symptom in older women.

Unfortunately, some patients do not seek medical attention despite months or years of heavy, irregular bleeding. In more advanced disease, pelvic pressure and pain may reflect uterine enlargement or extrauterine tumor spread. Patients with serous or clear cell tumors often present with signs and symptoms suggestive of advanced epithelial ovarian cancer. These include pelvic pain or pressure, bloating, early satiety, and increasing abdominal girth.

Papanicolaou Test

Pap testing is a screening test for cervical cancer. However, some findings from Pap testing should prompt further investigation for endometrial cancer. Benign endometrial cells are occasionally recorded on a routine Pap test report in women 45 years or older. In premenopausal women, this is often a finding of limited importance, especially if a test is obtained following menses. However, postmenopausal women with such findings have a 3- to 5-percent risk of endometrial cancer (Simsir, 2005). In those using HRT, the prevalence of benign endometrial cells on smears is greater, and the risk of endometrial malignancy

is low (1 to 2 percent) (Mount, 2002). Although endometrial biopsy is considered in asymptomatic postmenopausal women if this finding is reported, most patients ultimately diagnosed with hyperplasia or cancers also have concomitant abnormal bleeding (Ashfaq, 2001).

In contrast, *atypical glandular cells* found during Pap testing carry higher risks for underlying cervical or endometrial neoplasia. Accordingly, evaluation of a glandular abnormality includes colposcopy and endocervical curettage (ECC). It may also include endometrial sampling in nonpregnant patients older than 35 years. In those younger than 35 years, endometrial sampling is encouraged if AUB coexists, if patient risk factors for endometrial disease are present, or if the cytology report specifies that the atypical glandular cells are endometrial in origin.

Endometrial Sampling

Office Pipelle biopsy is preferred for the initial evaluation of women with bleeding suspicious for malignancy (Feldman, 1993). However, if sampling techniques fail to provide sufficient diagnostic information or if abnormal bleeding persists, D & C may be required to clarify the diagnosis.

The American College of Obstetricians and Gynecologists (2018a) considers hysteroscopy acceptable for AUB evaluation in those without advanced-stage uterine or cervical cancer. However, hysteroscopy is more sensitive for focal endometrial lesions and thus has proved less helpful in diagnosing early endometrial cancer. In those cases in which hysteroscopy is used to evaluate AUB and in which cancer is ultimately diagnosed, a higher incidence of positive peritoneal cytology has been noted during subsequent staging surgery (Obermair, 2000; Polyzos, 2010; Zerbe, 2000). Although the risk of peritoneal contamination by cancer cells may be increased by retrograde efflux of hysteroscopic media, patient prognosis overall does not appear to be worsened (Cicinelli, 2010; Revel, 2004).

Laboratory Testing

The only clinically useful tumor marker in the management of endometrial cancer is a serum CA125 level. Preoperatively, an elevated level indicates the possibility of more advanced disease (Powell, 2005). In practice, it is most useful in patients with advanced disease or serous subtypes to assist in monitoring response to therapy or during posttreatment surveillance. However, even in this setting, its utility in the absence of other clinical findings is limited (Price, 1998).

Imaging Studies

In general, for women with low-grade endometrial cancer, chest radiography may be considered. All other preoperative testing is directed toward general surgical preparation (Chap. 39, p. 822).

Computed tomography (CT) or magnetic resonance (MR) imaging is usually not necessary (American College of Obstetricians and Gynecologists, 2017b). However, CT scanning can be obtained preoperatively in cases with higher-grade lesions to assess for lymph node involvement or metastatic disease. MR imaging can occasionally help distinguish an endometrial cancer with cervical extension from a primary endocervical adenocarcinoma (Nagar, 2006). Women with serous features, carcinosarcoma, or other high-risk histology on preoperative biopsy and those with physical findings suggesting advanced disease are most appropriate for abdominopelvic CT scanning (Fig. 33-5). In these cases, advance knowledge of intraabdominal disease may help guide surgery and treatment. MR imaging is also recommended for women who are considering fertility-sparing management with hormonal therapy, because this may not be a suitable option if deep invasion is found.

Role of the Generalist

Although most endometrial cancers are cured by hysterectomy and BSO, primary management by gynecologic oncologists results in an efficient use of health-care resources, minimizes potential morbidity, is more likely to lead to staging, and improves the survival of patients with high-risk disease (Chan, 2011; Roland, 2004). Therefore, preoperative consultation is generally advisable for any patient with endometrial cancer who is being prepared for surgery by a generalist in obstetrics and

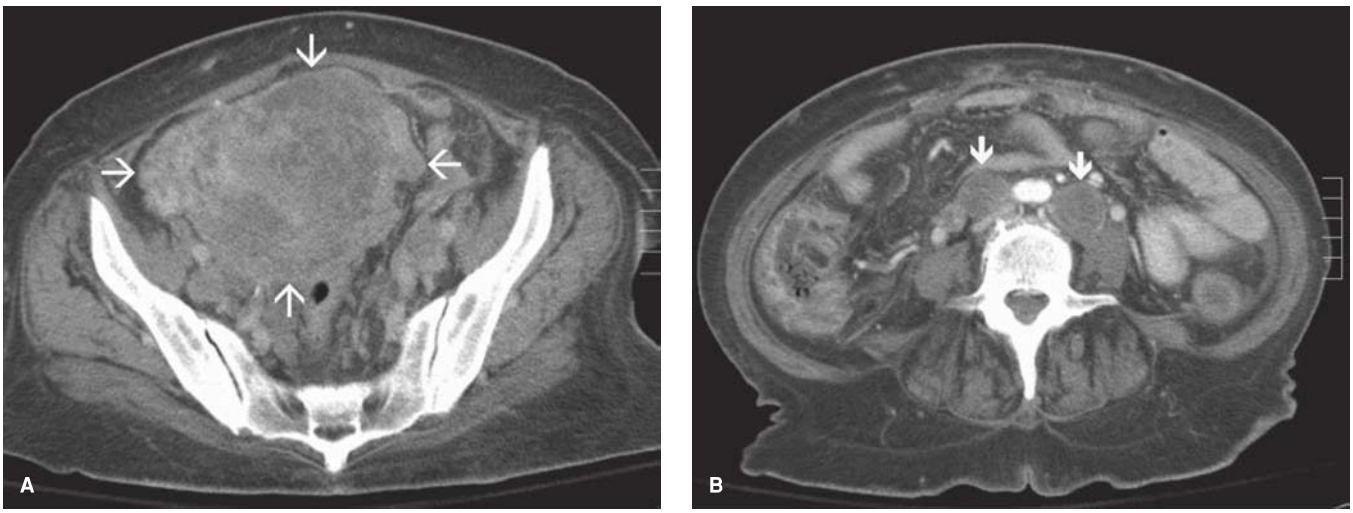

FIGURE 33-5 Computed tomographic (CT) images in the axial plane of a 61-year-old woman with endometrial cancer. **A.** Massively enlarged and inhomogeneous uterus (*arrows*) in the upper pelvis. **B.** At the level of the aortic bifurcation, enlarged lymph nodes are seen bilaterally (*arrows*), consistent with lymph node involvement. (Reproduced with permission from Dr. Diane Twickler.)

gynecology. Postoperatively, a gynecologic oncologist should be consulted if any extrauterine disease is found and if there is a question whether adjuvant therapy is indicated.

If treated by an oncologist, patients with early-stage cancer treated by surgery alone will return in many cases to their primary obstetrician-gynecologist for surveillance. Consultation is again recommended if recurrent disease is later suspected or identified.

When an endometrial cancer is unexpectedly diagnosed after hysterectomy performed by a generalist for other indications, consultation is recommended. Possible therapeutic options include no further therapy and surveillance only, reoperation to complete surgical staging, or radiotherapy to prevent local recurrence. In general, the survival advantages of staging must be weighed against the complications from another surgical procedure (American College of Obstetricians and Gynecologists, 2017b). Fortunately, the advent of laparoscopic and robotic delayed staging offers the potential for less morbidity than laparotomy (Spirtos, 2005).

Pathology

The spectrum of aggressiveness within the histopathologic types of endometrial cancer is broad (Table 33-5). Most patients have endometrioid adenocarcinomas that behave indolently. However, some will have an unfavorable histology that portends a much more aggressive tumor. In addition, the degree of tumor differentiation is an important predictor of disease spread.

Histologic Grade

The most widely used grading system for endometrial carcinoma is the three-tiered International Federation of Gynecology and Obstetrics (FIGO) system (Table 33-6). Grade 1 lesions typically are indolent with little propensity to spread outside the uterus or recur. Grade 2 tumors have an intermediate prognosis. Grade 3 cancers pose an increased potential for myometrial invasion and nodal metastasis.

Histologic grading is primarily determined by the tumor's architectural growth pattern (Zaino, 1994). However, there are exceptions, and the optimal method for determining grade is somewhat controversial. Nuclear atypia that is inappropriately advanced relative to the architectural grade raises a grade 1 or 2 tumor by one level. For example, a grade 2 lesion based on architectural features may be increased to a grade 3 lesion if significant nuclear atypia is present (Zaino, 1995). Nuclear grading based on the FIGO system is also used for all serous and clear cell adenocarcinomas (Pecorelli, 1999).

TABLE 33-6. Histopathologic Criteria for Assessing Grade

Grade	Definition
1	≤5% of a nonsquamous or nonmorular solid growth pattern
2	6–50% of a nonsquamous or nonmorular solid growth pattern
3	>50% of a nonsquamous or nonmorular solid growth pattern

Summarized from Pecorelli, 1999.

Histologic Type

Endometrioid Adenocarcinoma. This is the most common histologic type of endometrial cancer and accounts for more than 80 percent of cases. This type I tumor characteristically contains glands that resemble those of the normal endometrium (Fig. 33-6). The concomitant presence of hyperplastic endometrium correlates with a low-grade tumor and a lack of myometrial invasion. However, when the glandular component decreases and is replaced by solid nests and sheets of cells, the tumor is classified as a higher grade (Kurman, 2014). In addition, an atrophic endometrium is more frequently associated with high-grade lesions that have a greater potential to metastasize (Kurman, 1994).

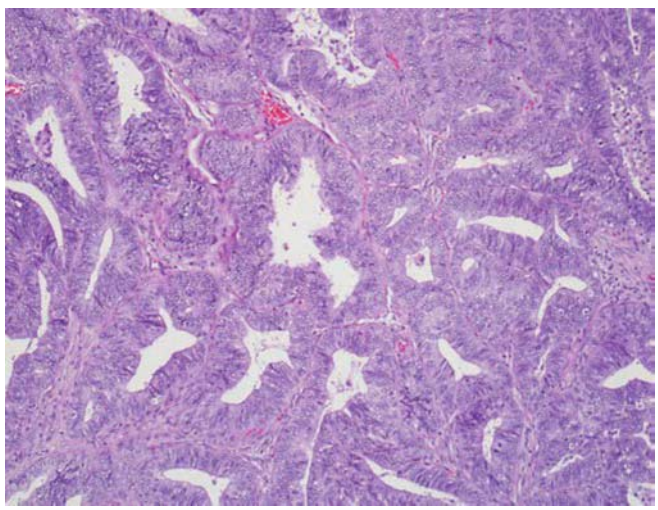

FIGURE 33-6 Endometrioid adenocarcinomas are composed of neoplastic glands resembling those of the normal endometrium. Cells are typically tall columnar with mild to moderate nuclear atypia. They form glands that are abnormally crowded or "back-to-back." Gland cribriforming, confluence, and villous structures also are common. It is these architectural forms, with the associated disappearance of intervening stroma, that distinguish well-differentiated endometrioid adenocarcinoma from atypical hyperplasia. (Reproduced with permission from Dr. Kelley Carrick.)

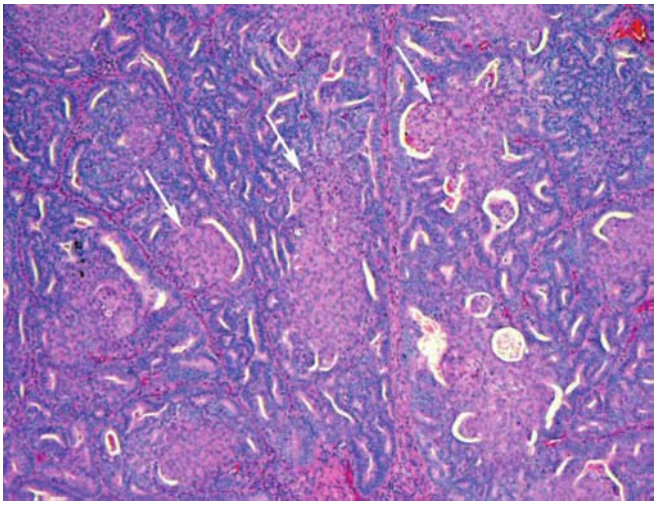

FIGURE 33-7 Endometrioid adenocarcinomas may show foci of squamous differentiation, which may be focal or relatively prominent. The squamous elements can have obvious squamous features such as keratinization or intercellular bridges or may be represented by less well-differentiated squamous morules (*arrows*), as in this example. (Reproduced with permission from Dr. Raheela Ashfaq.)

Endometrioid adenocarcinomas may also display variant forms. These include endometrioid adenocarcinoma with squamous differentiation and villoglandular, secretory, and ciliated cell types (Fig. 33-7). In general, the biologic behavior of these variant tumors reflects that of classic endometrioid adenocarcinoma.

Serous Carcinoma. Accounting for 5 to 10 percent of endometrial cancers, serous carcinoma typifies the highly aggressive type II tumors that arise from the atrophic endometrium of older women (Jordan, 2001). There is typically a complex pattern of papillary growth, and cells demonstrate marked nuclear atypia (Fig. 33-8). Commonly referred to as *uterine papillary serous carcinoma (UPSC)*, its histologic appearance resembles epithelial ovarian cancer, and psammoma bodies are seen in 30 percent of cases (Kurman, 2014).

Grossly, a papillary exophytic tumor emerges from a small, atrophic uterus. These tumors may occasionally be confined within a polyp and have no evidence for spread (Carcangiu, 1992). However, UPSC has a known propensity for myometrial and lymphatic invasion. Intraperitoneal spread, such as omental caking, which is unusual for typical endometrioid adenocarcinoma, also is common even when myometrial invasion is minimal or absent (Fig. 33-9) (Sherman, 1992). As a result, it may be impossible to distinguish UPSC from epithelial ovarian cancer during surgery. Like ovarian carcinoma, these tumors usually secrete CA125. Thus, serial serum measurements can be used to monitor disease postoperatively. UPSC is an aggressive cell type, and women with mixed endometrial cancers containing as little as 25 percent of UPSC have survival rates that mirror those with pure uterine serous carcinoma (Ellenson, 2011a).

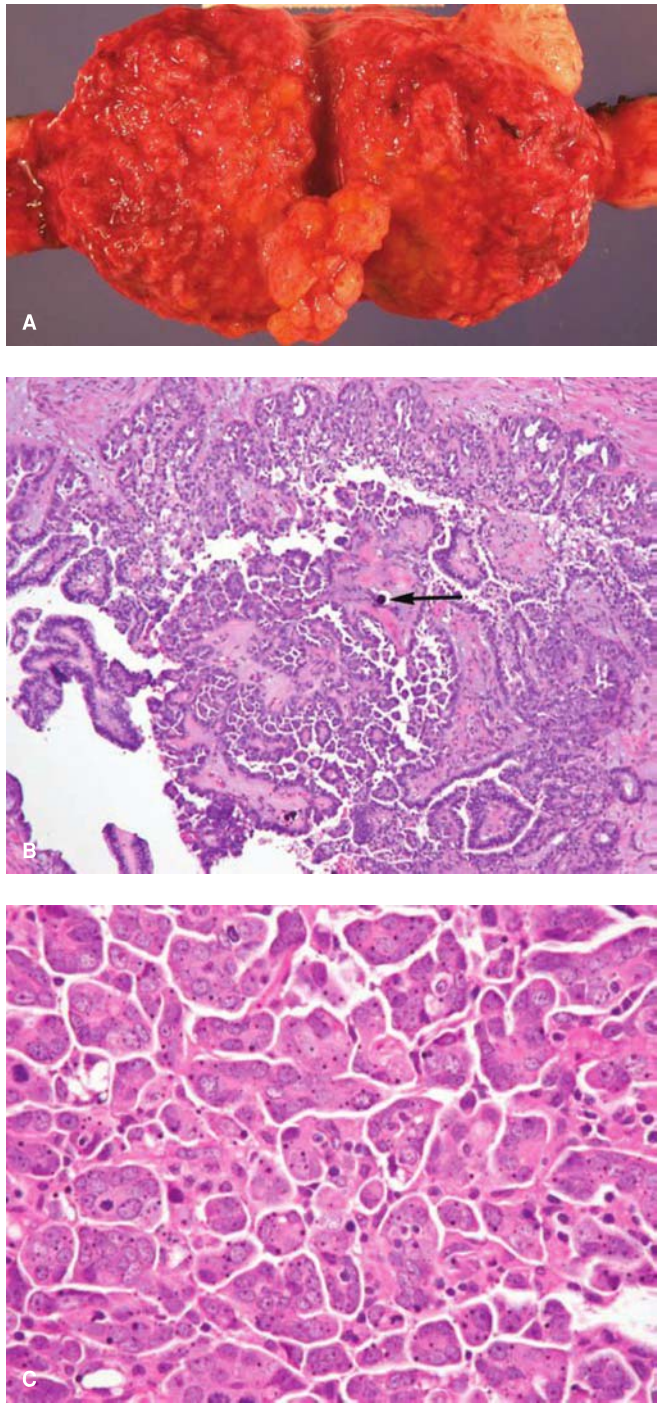

FIGURE 33-8 Uterine serous carcinoma. **A.** Uterine specimen. (Reproduced with permission from Dr. Raheela Ashfaq.) **B.** This tumor is typically characterized by a papillary architecture. Psammoma bodies, which are concentrically laminated calcifications (*arrow*), may be present. **C.** Cells are typically rounded as opposed to columnar. They have high-grade nuclear features including relatively large, pleomorphic nuclei; prominent nucleoli; and frequent, abnormal mitoses. (Reproduced with permission from Dr. Kelley Carrick.)

Carcinosarcoma. Carcinosarcomas are mixed tumors demonstrating both epithelial and stromal components. These have also been known as *malignant mixed müllerian tumor (MMMT)*. In the past, carcinosarcomas were classified as a type of uterine sarcoma, and the WHO classification still categorizes it as a mixed epithelial and mesenchymal tumor (Kurman, 2014). However, molecular studies have convincingly shown that most carcinosarcomas are monoclonal and driven by their

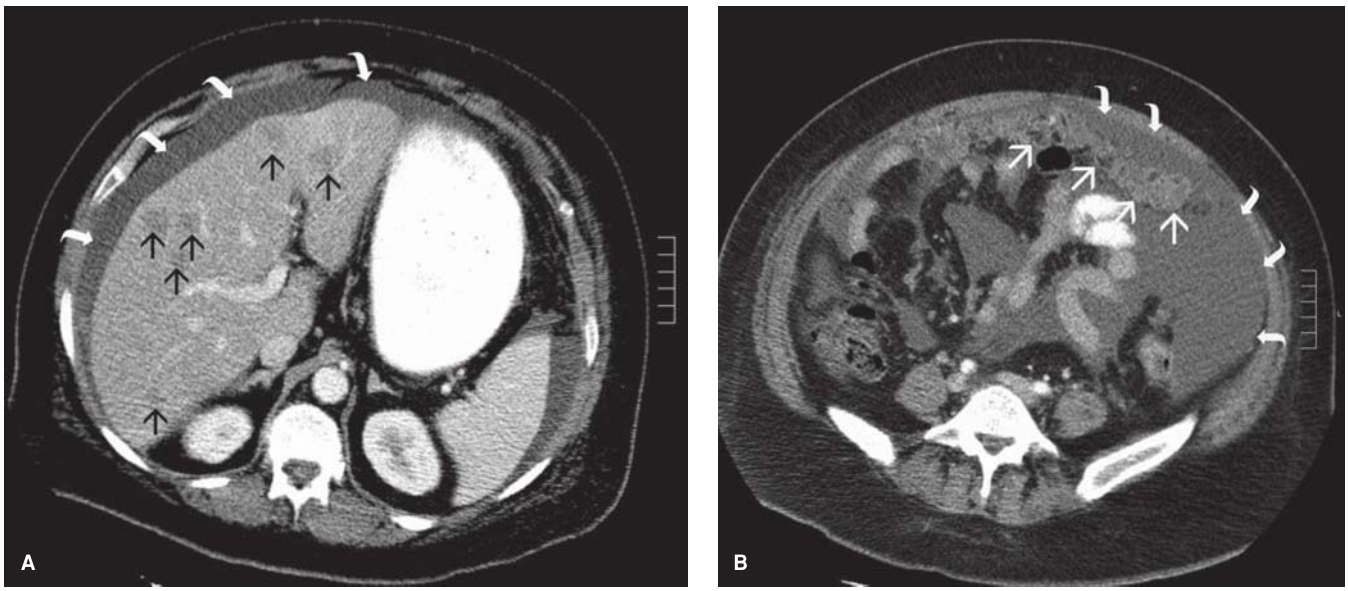

FIGURE 33-9 Computed tomographic (CT) images of liver metastases, ascites, and omental caking in a 51-year-old woman with endometrial cancer. **A.** Black arrows demarcate multiple low-density areas in the liver that are consistent with metastases, and ascites (*curved, white arrows*) surrounds the liver. **B.** A more caudal image reveals omental caking (*white arrows*) surrounded by massive ascites (*curved, white arrows*).

epithelial component (Wada, 1997). The sarcomatous element is thought to result from metaplasia of the epithelial element. Thus, these tumors generally behave like UPSC.

Grossly, the tumor is sessile or polypoid, bulky, necrotic, and often hemorrhagic (Fig. 33-10). It often fills the endometrial cavity and deeply invades the myometrium. On occasion, a large tumor protrudes through the external cervical os and fills the vaginal vault.

Microscopically, carcinosarcomas have an admixture of epithelial and mesenchymal differentiation. The malignant epithelial element is typically an adenocarcinoma of endometrioid type, but serous, clear cell, mucinous, squamous cell, and undifferentiated carcinoma also are common (Fig. 33-11). Mesenchymal components can be homologous to the uterus, usually resembling endometrial stromal sarcomas or fibrosarcomas. Alternatively, heterologous mesenchymal differentiation can be found in association with areas of endometrial stromal or undifferentiated sarcomas. Most commonly, rhabdomyosarcoma or chondrosarcoma compose these cases of heterologous mesenchymal differentiation (Fig. 33-12). Although interesting, the homologous or heterologous designation has no clinical importance.

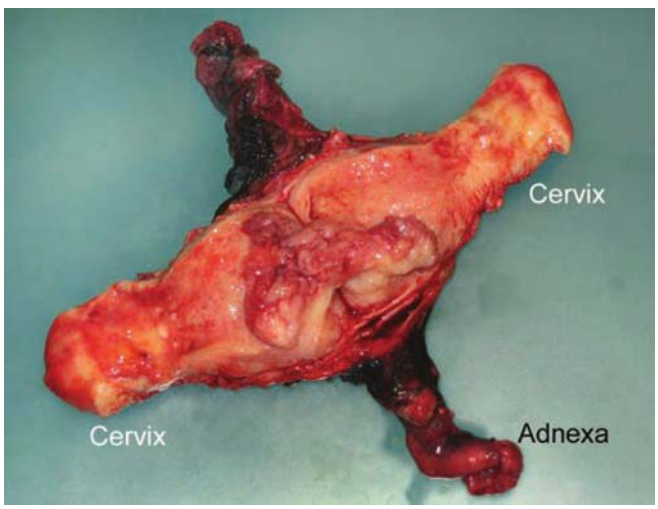

FIGURE 33-10 Carcinosarcoma. Photograph of the surgical specimen after it has been bisected and remains joined at the fundus.

With carcinosarcoma, endometrial sampling will often lead to a correct diagnosis, although in many cases only the carcinomatous features are evident. The reverse is also true, and occasionally a uterine carcinosarcoma is suspected based on endometrial biopsy findings, but no sarcomatous features are found within the hysterectomy specimen.

Their pattern of spread more closely mirrors that of UPSC. In addition, metastases usually show the serous carcinomatous elements, without sarcomatous differentiation. Patients are often older and have an average age of 65 years when diagnosed. Fewer than 5 percent are discovered in women younger than 50. At the time of diagnosis, approximately 40 percent are stage I. Stage II (10 percent), stage III (25 percent), and stage IV disease (25 percent) make up the remainder (Sartori, 1997; Vaidya, 2006).

Clear Cell Carcinoma. This is another type II tumor but is rare. The microscopic appearance may be predominantly solid, cystic, tubular, or papillary. Most frequently, it consists of a mixture of two or more of these patterns (Fig. 33-13).

Endometrial clear cell adenocarcinomas are similar to those arising in the ovary, vagina, and cervix. Grossly, there are no characteristic features, but like UPSC, they tend to be high-grade, deeply invasive tumors. Patients are often diagnosed with advanced disease and have a poor prognosis (Hamilton, 2006).

Mucinous Carcinoma. Of endometrial cancers, 1 to 2 percent have a mucinous appearance that forms more than half of the

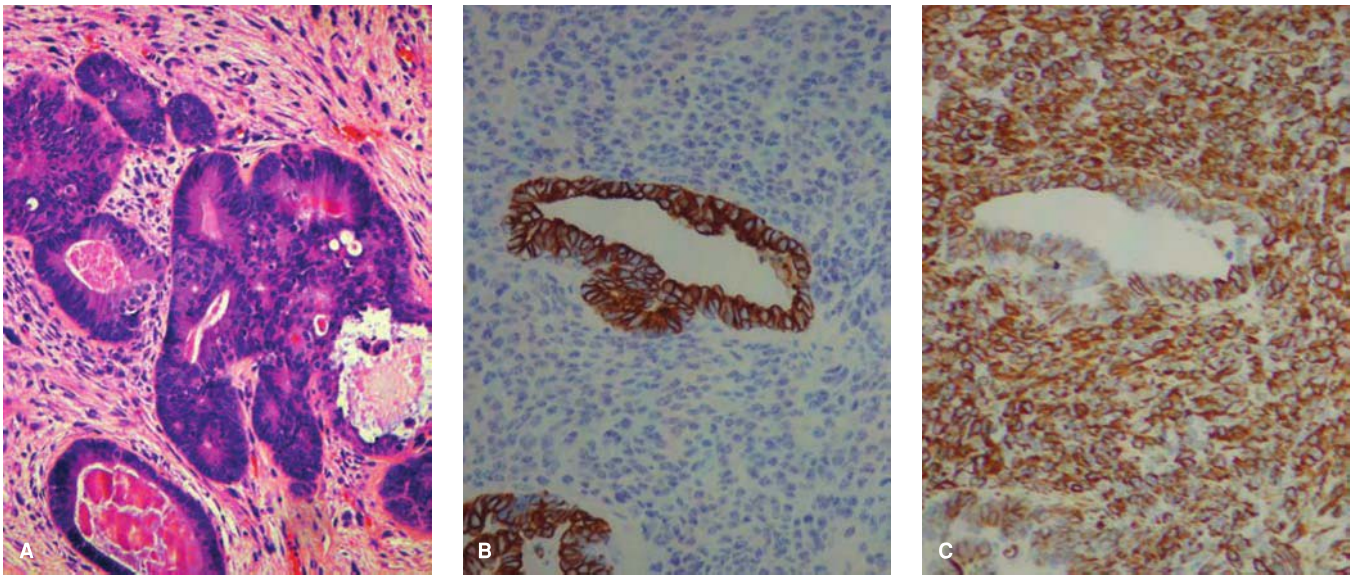

FIGURE 33-11 A. Carcinosarcoma is a biphasic malignant neoplasm composed of both carcinomatous and sarcomatous elements. In this example, malignant endometrioid-type glands are present within an atypical spindled stroma. **B.** Immunohistochemical stain for cytokeratin marks the epithelial component but not the stromal component. **C.** Conversely, an immunohistochemical stain for vimentin (a mesenchymal marker) stains the sarcomatous component. (Reproduced with permission from Dr. Raheela Ashfaq.)

tumor. However, many endometrioid adenocarcinomas will have this as a focal component (Ross, 1983). Typically, mucinous tumors have a glandular pattern with uniform columnar cells and minimal stratification (Fig. 33-14). Almost all are stage I grade 1 lesions and carry a good prognosis (Melhem, 1987). Since endocervical epithelium merges with the lower uterine segment, the main diagnostic dilemma is differentiating this tumor from a primary cervical adenocarcinoma. Immunostaining may be helpful, and MR imaging may further clarify the most likely site of origin. In general, to define anatomy, MR imaging is preferable to CT scanning as MR offers superior contrast resolution at soft-tissue interfaces.

Mixed Carcinoma, Undifferentiated Carcinoma, and Rare Types. An endometrial cancer may demonstrate combinations of two or more pure types. To be classified as a mixed carcinoma, a component must make up at least 10 percent of the tumor. Except for serous and clear cell histology, the combination of other types usually has no clinical significance. As a result, mixed carcinoma usually refers to an admixture of a type I (endometrioid adenocarcinoma and its variants) and a type II carcinoma (Kurman, 2014).

Undifferentiated carcinoma lacks architectural differentiation and is characterized by medium-sized, monotonous epithelial cells growing in solid sheets without a pattern (Silva, 2007).

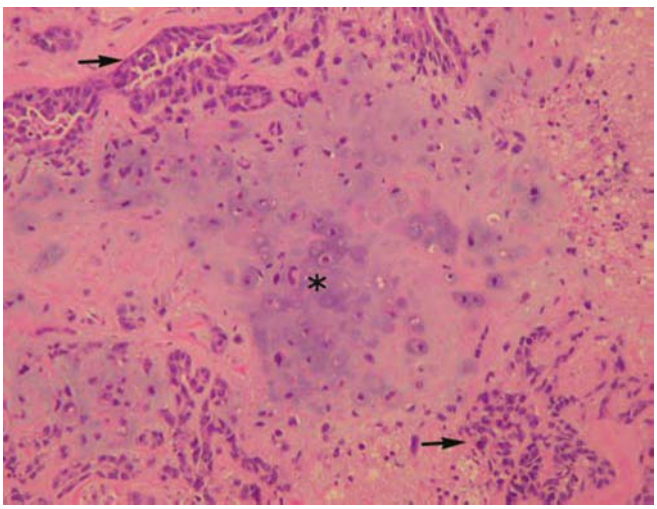

FIGURE 33-12 Carcinosarcoma with heterologous elements. In this carcinosarcoma with cartilaginous differentiation, malignant glands are present at the periphery (*arrows*). Centrally a focus of malignant cartilage (*asterisk*) is seen, with its characteristic lacunae embedded within a bluish chondroid matrix. (Reproduced with permission from Dr. Kelley Carrick.)

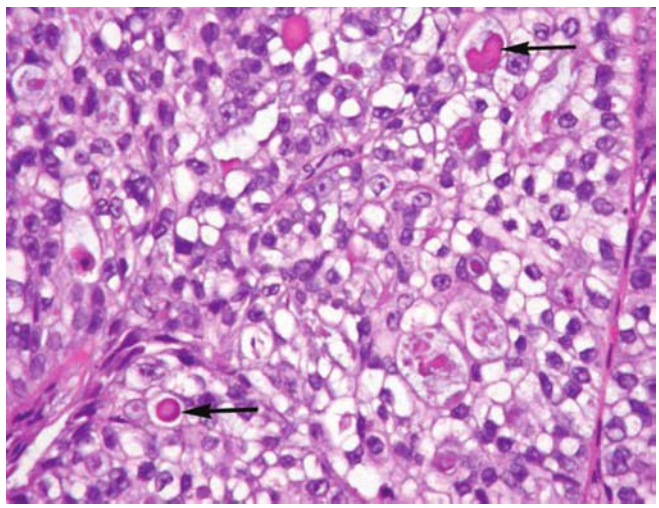

FIGURE 33-13 Clear cell adenocarcinomas are composed of cells with clear to eosinophilic granular cytoplasm. Cells are arranged in papillae, sheets, tubulocystic structures, or a combination. Eosinophilic hyaline globules (*arrows*) are a common feature. In this example, nuclei are moderately pleomorphic, with nucleolar prominence. (Reproduced with permission from Dr. Kelley Carrick.)

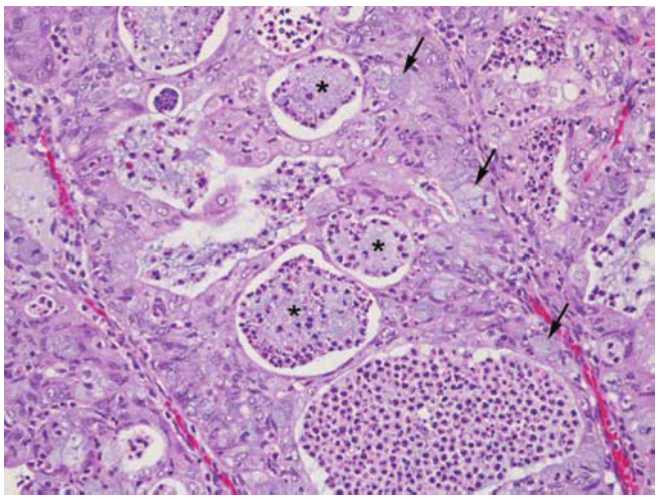

FIGURE 33-14 Mucinous adenocarcinoma of the endometrium has tumor cells containing intracytoplasmic mucin (*arrows*). Tumor cells form sheets and cribriform structures (*asterisks*), which in this example contain bluish mucin and numerous neutrophils. (Reproduced with permission from Dr. Kelley Carrick.)

These represent 1 to 2 percent of endometrial cancers. Overall, the prognosis is worse than in patients with poorly differentiated endometrioid adenocarcinomas (Altrabulsi, 2005). When an undifferentiated carcinoma has a component of low-grade endometrioid adenocarcinoma, these tumors are called *dedifferentiated carcinomas*.

Of rare histologic types, fewer than 100 cases of *squamous cell carcinoma* of the endometrium have been reported. Diagnosis requires exclusion of an adenocarcinoma component and no connection with the squamous epithelium of the cervix (Varras, 2002). Typically, the prognosis is poor (Goodman, 1996). *Transitional cell carcinoma* of the endometrium also is rare, and metastatic disease from the bladder or ovary must be excluded during diagnosis (Ahluwalia, 2006).

Patterns of Spread

Endometrial cancers have several different potential ways to spread beyond the uterus (Morrow, 1991). Type I endometrioid tumors and their variants most commonly spread, in order of frequency, by: (1) direct extension, (2) lymphatic metastasis, (3) hematogenous dissemination, and (4) intraperitoneal exfoliation. Type II serous and clear cell carcinomas and carcinosarcoma have a particular propensity for extrauterine disease, in a pattern that closely resembles epithelial ovarian cancer. In general, the various patterns of spread are interrelated and often develop simultaneously.

TABLE 33-7. Correlation of Histologic Grade and Depth of Myometrial Invasion in Stage I Patients ($n = 5095$)

Myometrial Invasion	Grade 1	Grade 2	Grade 3
None	29%	11%	15%
≤50%	51%	59%	46%
>50%	20%	30%	39%

Data from Creasman, 2006.

Invasion of the endometrial stroma and exophytic expansion within the uterine cavity follows initial growth of an early cancer. Over time, the tumor invades the myometrium and may ultimately perforate the serosa (Table 33-7). Tumors situated in the lower uterine segment tend to involve the cervix early, whereas those in the upper corpus tend to extend to the fallopian tubes or serosa. Advanced regional growth may lead to direct invasion into adjacent pelvic structures, including the bladder, large bowel, vagina, and broad ligament.

Lymphatic channel invasion and metastasis to the pelvic and paraaortic nodal chains can follow tumor penetration of the myometrium (Table 33-8). The lymphatic network draining the uterus is complex, and patients can have metastases to any single nodal group or combination of groups (Burke, 1996). This haphazard pattern is in contrast to cervical cancer, in which lymphatic spread usually follows a stepwise progression from pelvic to paraaortic to scalene nodal groups. Despite this, comprehensive surgical staging studies show that paraaortic nodal metastases in the absence of pelvic nodal metastases is infrequent, <2 percent (Boronow, 1984; Onda, 1997).

Hematogenous dissemination most commonly results in metastases to the lung and less commonly to the liver, brain, bone, and other sites. Deep myometrial invasion is the strongest predictor of this pattern of spread (Mariani, 2001a).

Retrograde transtubal transport of exfoliated endometrial cancer cells carries malignant cells to the peritoneal cavity. *Serosal perforation* of the tumor is another possible pathway. Most types of endometrial cancer cells found in the peritoneal cavity disappear within a short time and have low malignant potential (Hirai, 2001). Alternatively, in the presence of other high-risk features, such as adnexal metastases or serous histology, widespread intraabdominal disease may result.

TABLE 33-8. Correlation of Histologic Grade and Depth of Myometrial Invasion with Risk of Nodal Metastases

Myometrial Invasion	Pelvic Lymph Nodes G1	Pelvic Lymph Nodes G2	Pelvic Lymph Nodes G3	Paraaortic Lymph Nodes G1	Paraaortic Lymph Nodes G2	Paraaortic Lymph Nodes G3
None	1%	7%	16%	<1%	2%	5%
≤50%	2%	6%	10%	<1%	2%	4%
>50%	11%	21%	37%	2%	6%	13%

Data from Creasman, 2006.

Port-site metastasis is a rare but recognized method of cancer spread. Martínez and coworkers (2010) evaluated nearly 300 laparoscopic staging procedures for endometrial cancer. Port-site metastases complicated 0.33 percent of cases. Similarly, cancer dissemination following specimen morcellation has been reported (Graebe, 2015).

Treatment

Surgical Management

Most patients with endometrial cancer should undergo hysterectomy and BSO. The extent of surgical staging, including degree of lymph node assessment, is controversial. The National Comprehensive Cancer Network (NCCN) (2019) recently changed its guidance from recommending comprehensive pelvic and paraaortic lymphadenectomy in all patients to selective and tailored lymph node assessment, which may include sentinel lymph node biopsy.

For optimal patient management, the histopathologic description of the preoperative biopsy is carefully reviewed. Two thirds of patients are stage I at diagnosis (Fig. 33-15 and Table 33-9) (FIGO Committee on Gynecologic Oncology, 2009). Only a few circumstances contraindicate primary surgery and include a desire to preserve fertility, massive obesity, high operative risk, and clinically unresectable disease. In general, an extrafascial hysterectomy, also known as type I or simple hysterectomy, is sufficient. However, radical hysterectomy (type II or III hysterectomy) may be preferable

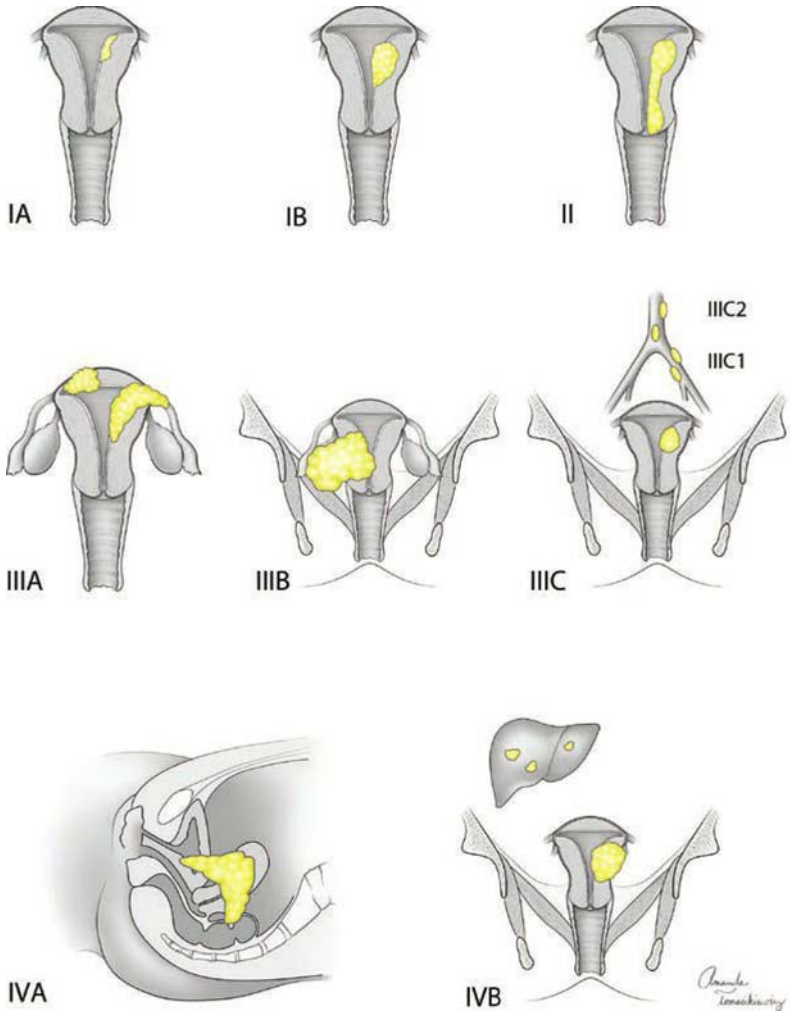

FIGURE 33-15 International Federation of Gynecology and Obstetrics (FIGO) staging of endometrial cancer.

TABLE 33-9. International Federation of Gynecology and Obstetrics (FIGO) Surgical Staging System for Endometrial Cancer

Stage[a]	Characteristics
I	**Tumor confined to the corpus uteri.**
IA	No or less than half myometrial invasion.
IB	Invasion equal to or more than half of the myometrium.
II	**Tumor invades cervical stroma but does not extend beyond the uterus[b].**
III	**Local and/or regional spread of the tumor.**
IIIA	Tumor invades the serosa of the corpus uteri and/or adnexae[c].
IIIB	Vaginal and/or parametrial involvement[c].
IIIC	Metastases to pelvic and/or para-aortic lymph nodes[c].
IIIC1	Positive pelvic nodes.
IIIC2	Positive paraaortic lymph nodes with or without positive pelvic lymph nodes.
IV	**Tumor invades bladder and/or bowel mucosa, and/or distant metastases.**
IVA	Tumor invasion of bladder and/or bowel mucosa.
IVB	Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes.

[a]Either G1, G2, or G3.
[b]Endocervical glandular involvement only should be considered as stage I and no longer as stage II.
[c]Positive cytology has to be reported separately without changing the stage.

for patients with clinically obvious cervical extension of endometrial cancer (Cornelison, 1999; Mariani, 2001b). Differences in these hysterectomy types are outlined in Table 30-7 (p. 666). Vaginal hysterectomy with or without BSO is another option for women who cannot undergo systematic surgical staging due to comorbidities (American College of Obstetricians and Gynecologists, 2017b). Previously, laparotomy had been the standard approach. However, laparoscopic and robotic surgical staging are increasingly used for endometrial cancer that appears clinically confined to the uterus. Such MIS staging is safe, feasible, and now recommended (Walker, 2009).

Regardless of approach, upon entering the peritoneal cavity, a thorough intraabdominal and pelvic exploration is performed, and suspicious lesions are biopsied or excised. Ascites, if present, is collected for cytologic study. These preliminary procedures are followed by hysterectomy and BSO. If the decision to perform lymphadenectomy is contingent on depth of myometrial invasion, this may be determined by intraoperative gross examination or microscopic frozen section analysis (Sanjuan, 2006; Vorgias, 2002).

As noted, the risk of lymph node metastasis correlates with the tumor grade and depth of invasion into the myometrium. Historically, the combination of preoperative biopsy grade and intraoperative assessment of the depth of myometrial invasion were the two factors that surgeons used to determine whether to proceed with pelvic and paraaortic lymph node dissection. The inaccuracy of this approach has been reported (Eltabbakh, 2005; Leitao, 2008; Papadia, 2009). In addition, the depth of myometrial invasion determined in the operative room is often inaccurate (Frumovitz, 2004a,b).

Lymphadenectomy may allow detection of positive nodes to guide appropriate treatment. Some retrospective studies showed improved survival rates in patients who had undergone an adequate lymph node dissection (Kilgore, 1995; Todo, 2010). However, the advantage appears to be confined to those in high-risk groups. To the contrary, authors of two randomized trials reported no improvement in disease-free or overall survival rates after lymphadenectomy in patients with early-stage disease (Benedetti Panici, 2008; Kitchener, 2009). These trials were criticized because lymph node counts were low and lymph node status did not dictate treatment, as many patients received postoperative radiation regardless of their lymph node status. Moreover, concern exists that omitting lymphadenectomy may lead to missed metastatic disease and subsequent insufficient postoperative treatment. Currently, many surgeons perform complete surgical staging with pelvic and paraaortic lymphadenectomy selectively and reserve this for patients with high-risk grade 1 endometrioid cancer and any case of grade 2, grade 3 or type II cancers. Using this approach, lymphadenectomy is omitted for low-risk patients.

Distinct from the above discussion, any suspicious pelvic or paraaortic lymph nodes should be removed and histologically evaluated. Excision of grossly involved lymph nodes may lead to a survival advantage (Havrilesky, 2005).

Those patients with serous, carcinosarcoma, or clear cell features on preoperative biopsy should have extended surgical staging with an infracolic omentectomy and bilateral peritoneal biopsies of the pelvis, pericolic gutter, and diaphragm (Bristow, 2001a). As in ovarian cancer, a surgeon is also prepared to resect any metastases (Bristow, 2000).

Recently, sentinel node biopsy (SLNB) has been cited as an acceptable replacement for lymphadenectomy in endometrial cancer by NCCN (2019) and the Society of Gynecologic Oncology (Holloway, 2017). According to the sentinel node paradigm, a cancer-free sentinel node should be highly predictive of negative nodes in the remainder of that nodal basin. Thus, complete lymphadenectomy could be avoided. Unlike vulvar cancer, the best technique for SLNB is debated for endometrial cancer, because these often lack a discrete tumor around which to inject dye (Fig. 31-9, p. 683). A common approach is to inject the cervix with a vital dye (Abu-Rustum, 2009). In most cases, at least one sentinel node on each side of the pelvis can be identified. If no sentinel node is identified, a side-specific lymphadenectomy is performed. Two prospective studies have demonstrated that SLNB has high sensitivity and high negative predictive value compared with lymphadenectomy (Ballester, 2011; Rossi, 2017). Many surgeons previously have limited SLNB use to type I endometrial cancers, but evidence is accumulating to support its use for more aggressive histologies, including serous carcinomas and carcinosarcomas (Schiavone, 2016, 2017; Soliman, 2017).

As noted, an MIS approach is acceptable for suitable candidates undergoing hysterectomy and staging for endometrial cancer (Childers, 1994; Spirtos, 2005). In the GOG LAP2 study, conventional open surgery plus pelvic/paraaortic lymphadenectomy was compared with the same steps completed laparoscopically for clinical stage I and IIA endometrial carcinoma. Investigators found laparoscopic staging to be feasible and safe (Walker, 2009). Laparoscopy was completed without conversion in 74 percent of patients randomized to MIS. Advantageously, compared with those undergoing laparotomy, patients undergoing laparoscopy had similar rates of intraoperative injuries (9 versus 8 percent), fewer moderate to severe complications (14 versus 21 percent), shorter hospital stays (median 3 versus 4 days), and better quality of life at 6 weeks postoperatively. However, laparoscopic staging was linked with longer operative times (Kornblith, 2009; Walker, 2009). Importantly, long-term treatment success does not appear to be compromised with laparoscopic surgery. Overall survival and recurrence rates in early reports are similar to those for a traditional open approach (Ghezzi, 2010; Magrina, 1999; Walker, 2012; Zullo, 2009). More recently, a randomized trial compared total laparoscopic hysterectomy to laparotomy in women with early-stage endometrial cancer (Janda, 2017). Selective pelvic (with or without paraaortic) lymphadenectomy was mandated unless the patient was morbidly obese or medically unfit. Disease-free and overall survival rates did not different between the two groups.

Robot-assisted laparoscopic staging of endometrial cancer has been embraced by many gynecologic oncologists to overcome MIS technical challenges, especially in obese patients. Early evidence shows it to be feasible and safe (Hoekstra, 2009). Compared with a laparoscopic approach for endometrial cancer staging, both major complication rates and mean number of lymph nodes removed are similar.

As described in Chapter 41 (p. 873), not all women are candidates for MIS. Limiting factors can include extensive adhesive

disease, a large bulky uterus, morbid obesity, cardiopulmonary disease, and other patient comorbidities. Importantly, morcellation is avoided in cancer cases to prevent disease spread.

Surveillance

Most surgically treated patients can simply be followed by pelvic examination every 3 to 6 months for the first 2 years and then every 6 to 12 months for 3 years (Salani 2017). Pap testing is not a recommended part of surveillance, as an asymptomatic vaginal recurrence is identified in <1 percent of patients (Bristow, 2006a; Cooper, 2006). Routine imaging also is not recommended. Patients should be made aware of symptoms that may indicate recurrence, particularly vaginal bleeding.

Women who have more advanced cancer that requires postoperative radiation or chemotherapy or both warrant more aggressive monitoring. Serum CA125 measurements may be valuable, particularly for UPSC, if the level was elevated prior to treatment. Intermittent imaging using CT scanning or MR imaging also may be indicated. In general, the pattern of recurrent disease depends on the original sites of metastasis and the treatment received.

Chemotherapy

Only three classes of cytotoxic drugs with definite activity for endometrial cancer have been identified, and paclitaxel (Taxol), doxorubicin (Adriamycin), and cisplatin (TAP) chemotherapy is one of the adjuvant treatment options for advanced endometrial cancer following surgery. In one GOG trial of 273 women (protocol #177), administration of seven courses of TAP was superior to doxorubicin plus cisplatin, but toxicity was increased, particularly peripheral neuropathy (Fleming, 2004). A less toxic alternative to TAP chemotherapy is paclitaxel plus carboplatin. Routinely used for ovarian cancer, this regimen is effective in advanced-stage endometrial cancer (Hoskins, 2001; Sovak, 2006, 2007). One GOG trial (protocol #209) compared TAP and the regimen of carboplatin plus paclitaxel. Results demonstrated that carboplatin plus paclitaxel was not inferior to TAP in terms of progression-free and overall survival rates. The toxicity profile favored carboplatin plus paclitaxel, and this regimen is generally used at our institution (Miller, 2012).

In practice, cytotoxic chemotherapy is frequently combined, sequenced, or sandwiched with radiotherapy in patients with advanced endometrial cancer following surgery. To reduce toxicity, directed pelvic or paraaortic radiation is usually employed rather than whole abdomen radiation (Homesley, 2009; Miller, 2009).

Radiation

Primary Radiation Therapy. This option rather than surgery is selected rarely and mainly for exceptionally poor surgical candidates. Intracavitary brachytherapy such as Heyman capsules with or without external beam pelvic radiation is the typical method (Chap. 28, p. 612). In general, the survival rate is 10 to 15 percent lower than that with surgical treatment (Chao, 1996; Fishman, 1996). These poor results suggest that a careful preoperative evaluation and appropriate consultation should be completed before any woman is denied the benefits of hysterectomy (American College of Obstetricians and Gynecologists, 2017b).

Adjuvant Radiation Therapy. In general, this option is offered after staging surgery to women at risk for endometrial cancer recurrence. Those with low-risk, early-stage cancer are typically adequately treated with surgery, may not benefit from adjuvant therapy, and usually simply begin surveillance.

In three major trials of stage I patients at intermediate risk, adjuvant radiation improved local disease control and recurrence-free survival rates. It did not decrease the rate of distant metastases or improve overall survival rates at 5 years (Aalders, 1980; Creutzberg, 2000, 2004; Keys, 2004).

However, in one of these trials, the recurrence rate reduction was particularly evident in a high-intermediate–risk subgroup of women: (1) with three risk factors (grade 2 or 3 tumors, lymphovascular invasion, and invasion of the outer third of the myometrium); (2) with age >50 years and two of these risk factors; and (3) with age >70 years and one risk factor (Keys, 2004). Therefore, adjuvant radiation is usually offered to patients with high-intermediate–risk stage I uterine cancers. The type of radiation offered is vaginal brachytherapy. The PORTEC-2 trial showed that vaginal brachytherapy compared with whole pelvic radiation offered equivalent recurrence rates but less toxicity in women with high-intermediate–risk endometrial cancer (Nout, 2010).

The aforementioned studies did not include patients with high-risk, early-stage disease, namely grade 3, deeply invasive cancers. These patients have traditionally been treated with whole pelvic radiation, and this remains a common practice. However, many patients still recur. Therefore, the PORTEC-3 trial was initiated to compare the benefit of adding chemotherapy during and after whole pelvic radiation to whole pelvic radiation alone in patients with high-risk stage I or locally advanced (stage II and III) disease. Chemotherapy consisted of cisplatin during weeks 1 and 4 of radiation, followed by four cycles of carboplatin and paclitaxel. Lymphadenectomy was optional. Preliminary results suggest that patients with high-risk stage I and stage II do not benefit from chemoradiation and are best treated with whole pelvic radiation alone (de Boer, 2017). However, women with stage III disease may benefit from the combined modality approach. For women with stage II endometrial cancer, the efficacy of postoperative radiotherapy is even harder to decipher. Most data derive from retrospective, single-institution experiences, and evidence supports external beam pelvic radiation, vaginal brachytherapy, both, or no further treatment (Cannon, 2009; Elshaikh, 2015; Rittenberg, 2005). As such, there is no standard approach, and most patients are treated individually based on coexisting risk factors (Feltmate, 1999). In general, patients who had radical hysterectomy are less likely to have pelvic radiation recommended to them postoperatively.

Chemotherapy is a treatment mainstay for patients with stage III or IV disease. This was established by GOG trial #122, in which patients with stage III or IV disease were randomly assigned following surgery to chemotherapy or whole abdomen radiation (Randall, 2006). The patients receiving chemotherapy had improved progression-free and overall survival rates.

GOG study #258 aimed to answer the important question of whether the addition of radiation to chemotherapy would result in improved outcomes compared with chemotherapy alone in

patients with stage III or IV, optimally debulked disease (Matei, 2017). At a median follow up of 47 months, recurrence-free and overall survival rates did not differ, although the latter results need more time to elapse to be considered final. Local and nodal control was improved in the chemoradiation arm, but distant control was improved in the chemotherapy arm. Acute toxicities were similar in the two arms. These results do not show a clear benefit to adding radiation in this population.

Hormonal Therapy

Cancer Treatment. One of the unique characteristics of endometrial cancer is its hormonal responsiveness. Thus, for women who are not surgical candidates, continuous chronic progestin treatment or a levonorgestrel-releasing IUD can be primary treatment (Dhar, 2005; Montz, 2002). In young premenopausal patients who desire fertility, similar primary progestin therapy can help reverse pathology (p. 703).

As adjuvant therapy, single-agent, high-dose progestins also have activity in women with advanced or recurrent disease (Lentz, 1996; Thigpen, 1999). Tamoxifen upregulates progesterone-receptor expression and is postulated to thereby improve progestin therapy efficacy. Clinically, tamoxifen used adjunctively with progestin therapy provides high response rates (Fiorica, 2004; Whitney, 2004). In general, toxicity is low, but this combination is most often used for recurrent disease. Aromatase inhibitors also have activity in endometrial cancer (Altman, 2012).

Estrogen Replacement Therapy. Due to the presumed role of excess estrogen in endometrial cancer development, estrogen supplementation following endometrial cancer treatment is often met with concern for stimulating malignancy recurrence. However, this effect has not been observed (Suriano, 2001). In one GOG study, 1236 women who had undergone surgery for stage I and II endometrial cancer were randomly assigned to receive either estrogen or placebo. Although the study did not meet its enrollment goals, the low recurrence rate (2 percent) was promising (Barakat, 2006). Women should be individually counseled regarding risks and benefits before beginning post-treatment estrogen replacement for menopausal symptoms.

Uterine Papillary Serous Carcinoma Management

This most aggressive type of endometrial carcinoma is rare, and thus, randomized trials are difficult to perform. As a result, most data are single-institution, retrospective analyses. Treatment is usually individualized but is often different from that for typical endometrioid adenocarcinoma.

If a preoperative biopsy demonstrates serous features, comprehensive surgical staging for UPSC is recommended. This includes total hysterectomy, BSO, peritoneal washings, pelvic/paraaortic lymph node dissection, infracolic omentectomy, and peritoneal biopsies (Chan, 2003). Even noninvasive disease is often widely metastatic (Gehrig, 2001). Fortunately, patients tend to have a good prognosis if surgical staging confirms that disease is confined to the uterus (stage I/II) (Grice, 1998).

Occasionally, no residual UPSC is evident on the hysterectomy specimen, or the tumor minimally involves the tip of a polyp. These women with surgical stage IA can safely be observed. However, all other patients with stage I disease are considered for adjuvant treatment. For this, one common strategy is postoperative paclitaxel and carboplatin chemotherapy for three to six cycles combined with concomitant vaginal brachytherapy (Dietrich, 2005; Kelly, 2005). However, some data suggest an intrinsic radioresistance for UPSC tumors (Martin, 2005). In addition, based on the largest retrospective review of patients with stage I disease, Huh and coworkers (2003) questioned the benefit of any radiation therapy.

Women with stage II UPSC are more likely to benefit from pelvic radiotherapy with or without chemotherapy following surgery. Those with stage III disease are especially prone to have recurrent disease at distant sites. Accordingly, paclitaxel and carboplatin is considered in addition to tumor-directed radiotherapy after surgery (Bristow, 2001a; Slomovitz, 2003).

In practice, many patients will have stage IVB disease. Aggressive surgical cytoreduction is likely to be important, because one of the strongest predictors of overall survival is the amount of residual disease. Postoperatively, at least six cycles of paclitaxel and carboplatin chemotherapy are indicated (Barrena-Medel, 2009; Bristow, 2001b; Moller, 2004). Enrollment in a clinical trial is strongly considered for cases of advanced uterine cancer.

Approximately 30 percent of serous endometrial cancers overexpress human epidermal growth factor receptor 2 (HER-2) and are potentially susceptible to therapies targeting HER-2. Trastuzumab (Herceptin) is a monoclonal antibody that targets HER-2. Compared with chemotherapy alone, this agent combined with chemotherapy improved the progression-free survival rate in patients with stage III or IV or recurrent serous carcinomas that overexpressed HER-2 (Fader, 2018).

Carcinosarcoma Management

For uterine carcinosarcoma, hysterectomy and BSO are mandatory. Lymph node metastases are found in up to one third of patients with clinical stage I disease. Thus, comprehensive lymphadenectomy should be performed as that done for poorly differentiated endometrial cancers (Major, 1993; Nemani, 2008; Park, 2010; Temkin, 2007). Typically, disease spread is histologically consistent with the carcinomatous element of this tumor.

Because of the high relapse risk even with early-stage carcinosarcoma, patients often receive adjuvant therapy. In one prospective trial, 224 women with all subtypes of stage I or II uterine sarcoma were randomly assigned to receive either pelvic radiation or no further treatment. For carcinosarcomas, a reduced rate of pelvic relapse was noted with radiotherapy, although survival rates were not improved (Reed, 2008). In one phase III study of 232 patients with stage I–IV carcinosarcoma, whole abdomen radiation was compared with ifosfamide plus cisplatin chemotherapy. Although no survival advantage was demonstrated, the observed differences favored combination chemotherapy use in future trials (Wolfson, 2007).

Ifosfamide has historically been the most active single agent for carcinosarcoma. The combination of ifosfamide and paclitaxel is the current preferred treatment for advanced or recurrent uterine carcinosarcoma (Galaal, 2013). In a phase III GOG trial that randomly assigned 179 patients, this regimen

demonstrated a superior response rate (45 versus 29 percent) and survival advantage compared with ifosfamide alone (protocol #161) (Homesley, 2007). The combination of carboplatin and paclitaxel also is active and is being compared with ifosfamide and paclitaxel in an ongoing GOG trial (protocol #261) (King, 2009; Powell, 2010).

Fertility-Sparing Management

Hormonal therapy without hysterectomy is an option in carefully selected young women with endometrial cancer who wish to preserve their fertility (Kim, 1997; Randall, 1997). Currently, patients considering fertility-sparing treatment are recommended to undergo a diagnostic hysteroscopy, sampling by D & C, and imaging to exclude deep myometrial invasion or extrauterine disease (Burke, 2014). Careful selection is also aided by a reproductive endocrinology consultation that clarifies the patient's posttreatment conception chances. Importantly, many of the biologic processes that lead to endometrial cancer also contribute to decreased fertility. In general, this strategy should apply only to those with grade 1 (type I tumor) adenocarcinomas and with no imaging evidence of myometrial invasion. The aim of hormonal treatment is to reverse the lesion. However, any type of medical management obviously involves inherent risk that a patient must be willing to accept (Yang, 2005).

Progestins are most commonly used for conservative treatment. Oral megestrol acetate, 160 mg daily or 80 mg twice daily, can promote cancer regression. Alternatively, oral or intramuscular MPA may be delivered at varying doses (Gotlieb, 2003). The levonorgestrel-releasing IUD is another acceptable option. Combining progestin therapy with tamoxifen or with gonadotropin-releasing hormone agonists is less frequently done (Wang, 2002). Regardless of the hormonal agent, recurrence rates are high during long-term observation (Gotlieb, 2003; Niwa, 2005).

Women receiving fertility-sparing management are carefully monitored by repeated endometrial biopsy or D & C every 3 months to assess treatment efficacy. Evidence for persistence often prompts a change in agent or a dose increase. Hysterectomy and operative staging is recommended if a lesion fails to regress with hormonal therapy or if disease progression is suspected.

Delivery of a healthy infant is a reasonable expectation for those patients who respond to treatment and have normal histologic findings in surveillance endometrial samplings. However, assisted reproductive technologies may be required to achieve pregnancy in some cases. Postpartum, patients are again regularly monitored for recurrent endometrial adenocarcinoma (Ferrandina, 2005). In general, women should undergo hysterectomy at completion of childbearing or whenever the preservation of fertility is no longer desired.

Prognostic Factors

Many clinical and pathologic factors influence the likelihood of endometrial cancer recurrence and survival (Table 33-10) (Lurain, 1991; Schink, 1991). FIGO surgical stage is the most important overriding variable because it incorporates many of the most important risk factors (Table 33-11). Cases with no myometrial invasion and <50 percent invasion are considered stage IA. Stage IB includes cases with >50 percent myometrial invasion, but cancer has not spread outside the uterine corpus. Stage II now includes cases with only cervical stromal invasion, since cervical gland involvement alone does not worsen prognosis. Stage III no longer includes positive peritoneal washings since this does not appear to alter prognosis. Stage IIIC is now subdivided into IIIC1 and IIIC2, reflecting the worse prognosis associated with paraaortic lymph node involvement as opposed to pelvic only. Stage IV now includes locally advanced disease, including to the lower vagina or pelvic sidewall. One important prognostic factor not captured by FIGO stage is lymphovascular space invasion (Bosse, 2015).

TABLE 33-10. Poor Prognostic Variables in Endometrial Cancer

Advanced surgical stage
Older age
Histologic type: UPSC or clear cell adenocarcinoma or carcinosarcoma
Advanced tumor grade
Presence of myometrial invasion
Presence of lymphovascular space invasion
Peritoneal cytology positive for cancer cells
Increased tumor size

ER = estrogen receptor; PR = progesterone receptor; UPSC = uterine papillary serous carcinoma.

Recurrent Disease

Patients with recurrent endometrial cancer typically require individualized treatment. In general, the site of relapse is the most important predictor of survival. Depending on the circumstances, surgery, radiation, chemotherapy, or a combination may be used. The most curable scenario is an isolated

TABLE 33-11. Carcinoma of the Uterine Corpus 5-year Survival Rates for Each Surgical Stage

FIGO Stage	5-Year Relative Survival Rate[a]
IA	88%
IB	75%
II	69%
IIIA	58%
IIIB	50%
IIIC	47%
IVA	17%
IVB	15%

[a]Data from 21,904 cases.

Data compiled from the American Joint Committee on Cancer, 2010.

relapse at the vaginal apex in a previously unradiated patient. These women are usually effectively treated by external beam pelvic radiotherapy. In patients who were previously irradiated, exenteration is often the only curative option (Section 46-4, p. 1174) (Barakat, 1999; Morris, 1996). Nodal recurrences or isolated pelvic disease is more likely to result in further disease progression, regardless of treatment modality. However, either is often an appropriate indication for external beam radiotherapy in those not previously irradiated. Salvage cytoreductive surgery also may be beneficial in selected patients (Awtrey, 2006; Bristow, 2006b).

Widely disseminated endometrial cancer or a relapse not amenable to radiation or surgery is an indication for systemic chemotherapy (Barrena-Medel, 2009). Patients are ideally enrolled in an experimental trial due to the limited duration of response with current salvage regimens and the urgent need for more effective therapy. Paclitaxel and carboplatin is an active combination for recurrent disease and found not to be inferior to TAP (Miller, 2012). An alternative regimen, the combination of the aromatase inhibitor letrozole and the mammalian target of rapamycin (mTOR) inhibitor everolimus, has significant activity in recurrent endometrial cancer (Slomovitz, 2015). Progestin therapy with or without tamoxifen is a less toxic option that is particularly useful in selected cases (Fiorica, 2004; Whitney, 2004). Finally, the PD-1 inhibitor pembrolizumab was recently approved by the FDA for any recurrent tumor, of any origin, with high microsatellite instability (MSI-H) (Ott, 2017). This new biologic agent is more fully described in Chapter 27 (p. 601). Therefore, patients with recurrent endometrial cancer for whom systemic therapy is indicated should have their tumors tested for MSI-H. In general, effective palliation of women with incurable, recurrent endometrial cancer requires an ongoing dialogue to achieve the optimal balance between symptomatic relief and treatment toxicity.

Malignant tumors of the uterine corpus are broadly divided into carcinomas and sarcomas. Although sarcomas are rarely encountered, they tend to behave more aggressively and contribute to a disproportionately higher number of uterine cancer deaths. Pure sarcomas differentiate toward smooth muscle (leiomyosarcoma) or toward endometrial stroma (endometrial stromal tumors). In general, uterine sarcomas grow quickly, hematogenous or lymphatic spread occurs early, and the overall prognosis is poor. However, there are several notable exceptions among these tumors.

EPIDEMIOLOGY AND PATHOGENESIS

Sarcomas account for approximately 3 to 8 percent of all malignancies of the uterine corpus (Brooks, 2004; D'Angelo, 2010; Major, 1993). Historically, uterine sarcomas included carcinosarcomas, accounting for 40 percent of cases; leiomyosarcomas, 40 percent; endometrial stromal sarcomas, 10 to 15 percent; and undifferentiated sarcomas, 5 to 10 percent. In 2009, the International Federation of Gynecology and Obstetrics (FIGO) reclassified carcinosarcomas as a metaplastic form of endometrial carcinoma. These tumors are described in Chapter 33 (p. 708).

Because of their infrequency, uterine sarcomas have few identified risk factors. These include chronic excess estrogen exposure, tamoxifen use, African American race, and prior pelvic radiation. In contrast, combination oral contraceptive pill use and smoking appear to lower risks for some of these tumors (Felix, 2013).

In their pathogenesis, *leiomyosarcomas* have a monoclonal origin, and for the most part, they do not arise from benign leiomyomas. Instead, they appear to develop de novo as solitary lesions (Zhang, 2006). Supporting this theory, leiomyosarcomas have molecular pathways distinct from those of leiomyomas or normal myometrium (Cui, 2017). The most consistent findings across molecular studies involve functional loss of *RB1* and *PTEN*, which are tumor suppressor genes (El-Rifai, 1998; Gibault, 2011).

Endometrial stromal tumors have heterogeneous chromosomal aberrations (Halbwedl, 2005). However, the pattern of rearrangements is clearly nonrandom, and chromosomal arms 6p and 7p are frequently involved (Micci, 2006). Genetic translocations involving several chromosomes and the resultant fusion proteins are thought to be involved in endometrial stromal sarcoma pathogenesis (Lee, 2012; Panagopoulos, 2012).

DIAGNOSIS

Signs and Symptoms

As in endometrial cancer, abnormal vaginal bleeding is the most frequent symptom for uterine sarcomas (Gonzalez-Bosquet, 1997). Pelvic or abdominal pain also is common. Up to one third of women will describe significant discomfort that may result from passage of clots, rapid uterine enlargement, or prolapse of a sarcomatous polyp through an effaced cervix (De Fusco, 1989). In addition, a profuse, foul-smelling discharge may be obvious, and gastrointestinal and genitourinary complaints are frequent. Importantly, degenerating leiomyomas with necrosis can mimic these same signs and symptoms.

With rapid growth, a uterus may extend out of the pelvis into the mid- or upper abdomen (Fig. 34-1). Fortunately, the incidence of malignancy in such cases is low (<0.5 percent), and in most instances, benign enlarging leiomyomas are found (Leibsohn, 1990; Parker, 1994). Although uterine leiomyosarcomas do tend to grow quickly, no criteria define what constitutes significant growth. Despite these often-dramatic presentations, many women with uterine sarcoma will have few symptoms other than abnormal vaginal bleeding and a seemingly normal uterus on physical examination.

Endometrial Sampling

The sensitivity of an office endometrial biopsy or dilation and curettage (D & C) to detect sarcomatous elements is lower than that for endometrial carcinomas (Bansal, 2008). Specifically, with leiomyosarcoma, symptomatic women receive a correct preoperative diagnosis in only 35 to 50 percent of cases (Hinchcliff, 2016). This inability to accurately sample the tumor is probably related to the origin of these neoplasms in the myometrium rather than the endometrium. Similarly,

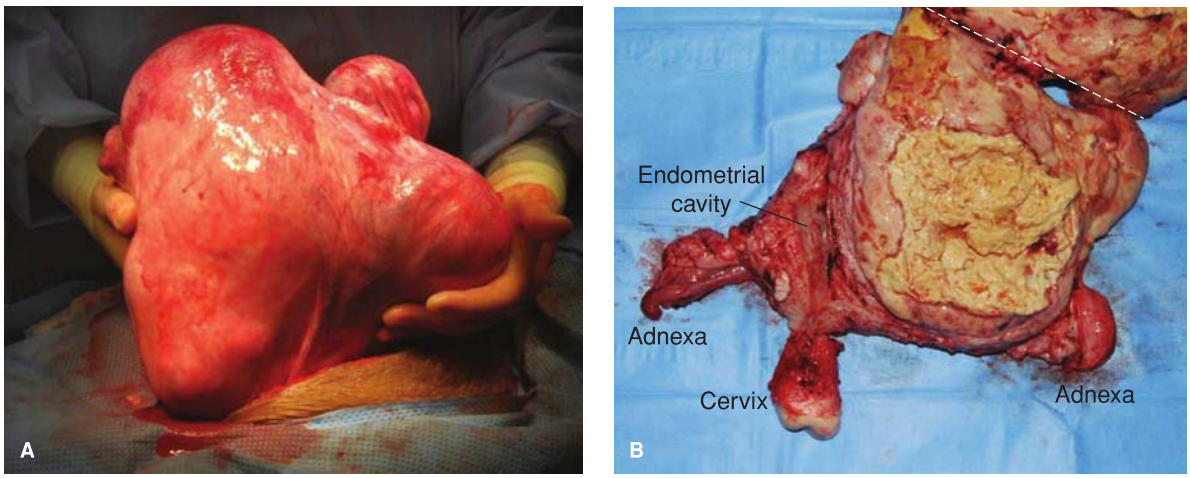

FIGURE 34-1 Leiomyosarcoma. **A.** Intraoperative photograph. **B.** Surgical specimen has been bisected and remains joined at the fundus. The other half of the specimen lies above the white dashed line and out of view. The large tumor lies to the right of the endometrial cavity. It has central necrosis seen as yellow amorphous debris within the tumor borders. (Reproduced with permission from Dr. Martha Rac.)

endometrial stromal nodules and endometrial stromal sarcoma may be undetectable by Pipelle biopsy, especially if the neoplasm is intramural (Yang, 2002).

Imaging Studies

These are often helpful if sarcoma is suspected before hysterectomy. In most cases, a computed tomography (CT) scan of the abdomen and pelvis is routinely performed. This serves at least two purposes. First, sarcomas often violate normal soft tissue planes in the pelvis, and therefore, unresectable tumors may be identified preoperatively. Second, extrauterine metastases may be found. In either case, treatment may be altered based on radiographic findings.

Diffusion weighted magnetic resonance (MR) imaging may be more diagnostic in distinguishing uterine sarcoma from a benign "mimic" (DeMulder, 2018; Sumi, 2015). As a diagnostic tool for sarcoma, sonography is far less helpful. Positron emission tomography (PET) scanning is most effective in the setting of recurrent uterine sarcoma but offers little advantage compared with CT or MR imaging (Sharma, 2012).

Role of the Generalist

Preoperative consultation with a gynecologic oncologist is recommended for any patient with a biopsy suggesting uterine sarcoma. The potential for intraabdominal metastases and disruption of tissue planes within the pelvis increases the technical difficulty and surgical risks. The approach to staging is subtly dissimilar to that of endometrial carcinomas. For example, due to the low rate of metastasis, only sampling nodes suspicious for leiomyosarcomas may be appropriate instead of performing complete pelvic and paraaortic lymphadenectomy (Nasioudis, 2019). Moreover, ovarian preservation may be suitable with certain sarcomas because of their low risk for spread to the adnexa, but not in others. In general, a treatment plan is best organized preoperatively, if possible.

Many uterine sarcomas are not diagnosed until surgery or several days later when a pathology report is available. As a result, unstaged cases are common, and a gynecologic oncologist should be consulted at the earliest feasible time. If the diagnosis is made postoperatively, the criteria to recommend surveillance only, reoperation, or radiotherapy vary widely and depend on the sarcoma type and other clinical circumstances. Generally, these options are less straightforward than in typical endometrial carcinomas, largely due to the rarity of these tumors and the comparatively limited data supporting one strategy over another.

With adoption of minimally invasive surgery (MIS), gynecologists are faced with how best to achieve removal of bulky uteri or myomas through small incisions. Tissue fragmentation using laparoscopic power morcellation was a popular approach, until the increased concerns about dispersion of clinically occult gynecologic cancers became more evident. In particular, encountering an unexpected uterine sarcoma during surgery for presumed benign disease is rare, and rates range from 0.09 to 0.6 percent (Kho, 2016; Lieng, 2015; Multinu, 2019). These investigators also

TABLE 34-1. Histologic Classification of Mesenchymal Tumors of the Uterus

found no clear preoperative risk factors. However, if a patient undergoes inadvertent morcellation and dispersion of an occult sarcoma, it may worsen her prognosis (Perri, 2009). In 2018, the Food and Drug Administration warned that power morcellator use should be curtailed in patients who are peri- or postmenopausal or who are candidates for en bloc removal through the vagina or a minilaparotomy. At minimum, if uncontained intraperitoneal morcellation is selected by those at low risk for cancer, patients should be aware of the risks that it poses (American College of Obstetricians and Gynecologists, 2019).

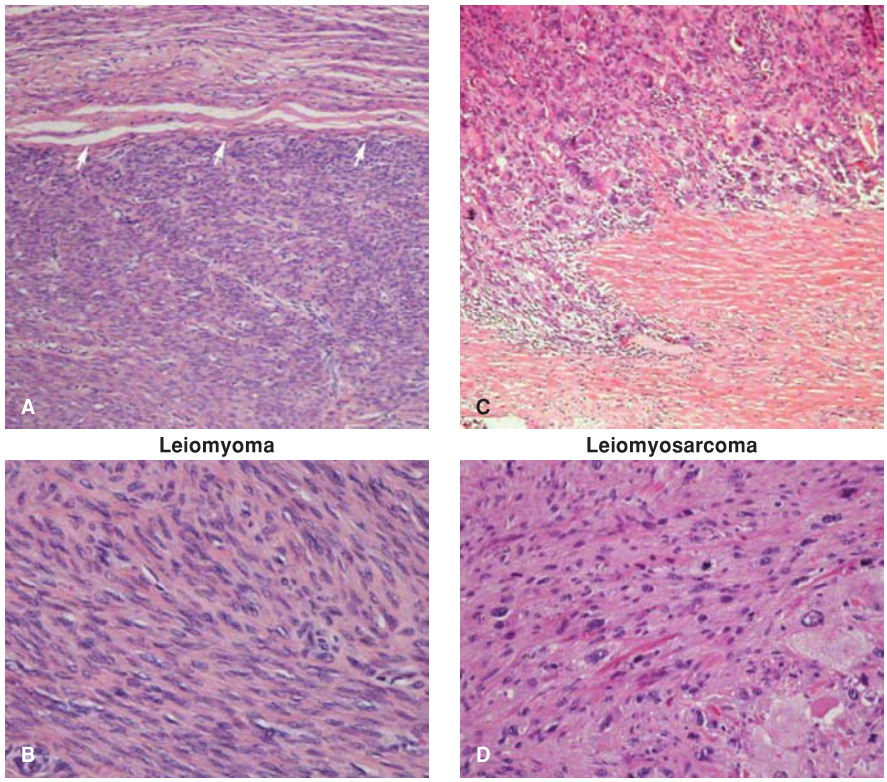

FIGURE 34-2 Leiomyoma **(A, B)** and leiomyosarcoma **(C,D)**. **A.** Leiomyomas tend to be well-circumscribed masses. This leiomyoma shows a well-demarcated interface (*arrows*) with the less cellular myometrium above it. **B.** Although leiomyomas may have variable histologic features, most are composed of bland spindled cells with blunt-ended nuclei and limited mitotic activity. **C.** Leiomyosarcoma is a malignant smooth muscle neoplasm that may differ markedly in its microscopic appearance from case to case. Generally, leiomyosarcoma shows some combination of coagulative tumor necrosis, increased mitotic activity, and/or nuclear atypia. This example has marked nuclear atypia and pleomorphism and an infiltrative growth pattern at its periphery. This differs from the usually smooth, pushing border of typical leiomyomas. **D.** This particular example has moderate to marked nuclear atypia. (Reproduced with permission from Drs. Kelley Carrick and Raheela Ashfaq.)

PATHOLOGY

Uterine mesenchymal tumors are classified broadly into pure and mixed tumors (Table 34-1). Also, the term *homologous* denotes tissues normally found in the uterus and *heterologous* refers to tissue foreign to the uterus. Pure sarcomas are virtually all homologous and differentiate into mesenchymal tissue that is normally present within the uterus, such as smooth muscle (leiomyosarcoma) or stromal tissue within the endometrium (endometrial stromal tumors). Pure heterologous sarcomas, such as chondrosarcoma, are rare.

Mixed sarcomas contain a malignant mesenchymal component admixed with an epithelial element. If the epithelial element is also malignant, the tumor is termed *carcinosarcoma*. If the epithelial element is benign, the term *adenosarcoma* is used.

Leiomyosarcoma

Leiomyosarcomas account for 1 to 2 percent of all uterine malignances. In two Surveillance, Epidemiology, and End Results (SEER) database studies, the median age at presentation was 52 and 50 years, respectively (Hosh, 2016; Kapp, 2008). Most tumors were localized at the time of diagnosis, whereas 3 to 14 percent had regional disease. Distant disease composed 7 to 31 percent.

The Stanford criteria are the commonly used histologic criteria for diagnosing leiomyosarcoma. They are somewhat controversial but include the frequency of mitotic figures, extent of nuclear atypia, and presence of coagulative tumor cell necrosis (Fig. 34-2) (Bell, 1994). In reading Table 34-2, each row illustrates combinations of histologic findings that may be found in leiomyosarcomas. In most cases, the mitotic index exceeds 15 mitotic figures total when 10 high-power fields are examined, moderate to severe cytologic atypia is seen, and tumor cell necrosis is prominent (Oliva, 2014b; Zaloudek, 2011). Occasionally, a leiomyosarcoma will be reported as low-, intermediate-, or high-grade, but the overall utility of grading is controversial, and no grading system is universally accepted.

Smooth Muscle Tumor of Uncertain Malignant Potential (STUMP)

These are tumors with some worrisome histologic features, such as necrosis or nuclear atypia, but without criteria to be

TABLE 34-2. Diagnostic Criteria for Uterine Leiomyosarcoma

Coagulative Tumor Cell Necrosis	Mitotic Index[a]	Degree of Atypia
Present	≥10 MF/10 HPF	None
Present	Any	Diffuse, significant
Absent	≥10 MF/10 HPF	Diffuse, significant

[a]MF/10 HPF = the total number of mitotic figures counted when 10 high-powered fields are examined.

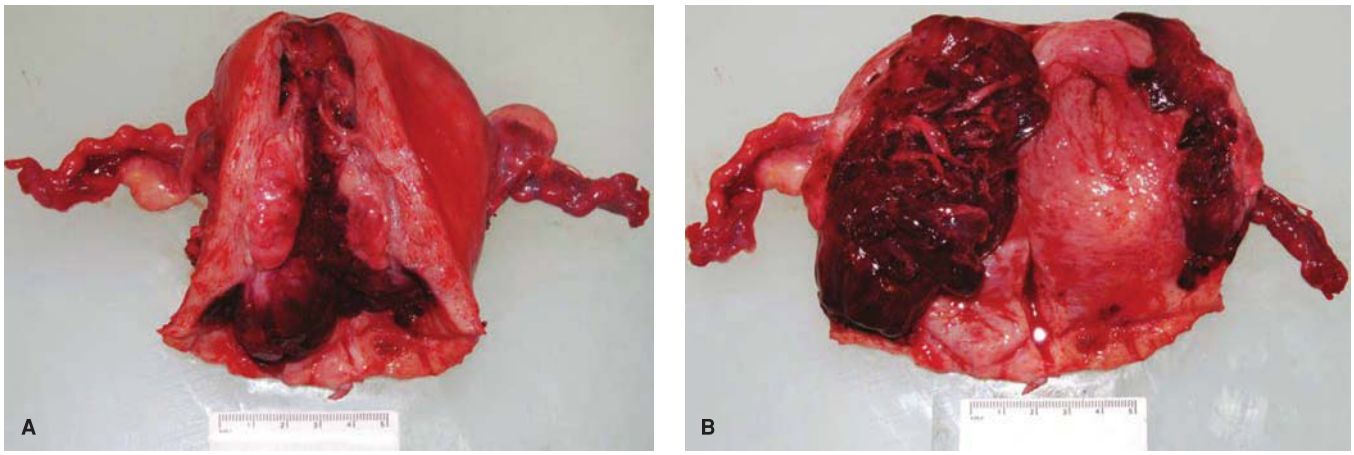

FIGURE 34-3 Gross uterine specimen with endometrial stromal sarcoma. **A.** The mass partially prolapsed through the cervix. **B.** Opened uterine specimen.

diagnosed reliably as benign or malignant. The diagnosis should be used sparingly and is reserved for smooth muscle neoplasms whose appearance is ambiguous (Oliva, 2014b).

Endometrial Stromal Tumors

Significantly less common than leiomyosarcomas, the group of endometrial stromal tumors represent fewer than 10 percent of all uterine sarcomas. In a SEER database study of 831 patients, the median age at diagnosis was 52 years (Chan, 2008). Although constituting a wide morphologic spectrum, endometrial stromal tumors are composed exclusively of cells that resemble the endometrial stroma.

Historically, there has been controversy in subdividing these tumors. The division of endometrial stromal sarcomas into low-grade and high-grade categories has fallen out of favor. In its place, the designation *endometrial stromal sarcoma* is now best restricted to neoplasms that were formerly referred to as low-grade. Alternatively, the term *high-grade undifferentiated sarcoma* is believed to more accurately reflect those tumors without recognizable evidence of a definite endometrial stromal phenotype. These lesions often resemble the mesenchymal component of a uterine carcinosarcoma and in this revised classification, the distinctions are not determined by mitotic count but by features such as nuclear pleomorphism and necrosis (Oliva, 2014a,b).

Endometrial Stromal Nodule

Representing less than a quarter of tumors in the endometrial stromal tumor group, these rare nodules are benign, characterized by a well-delineated margin, and composed of neoplastic cells that resemble proliferative-phase endometrial stromal cells. Grossly, the tumor is a solitary, round or oval, fleshy nodule measuring a few centimeters. Histologically, they are distinguished from endometrial stromal sarcomas by their lack of myometrial infiltration (Hoang, 2018). Because these nodules are benign, myomectomy is an appropriate option. However, because differentiation between endometrial stromal sarcoma and this benign lesion cannot be determined clinically, it is important to remove the entire nodule. Thus, for large lesions, hysterectomy may be required.

Endometrial Stromal Sarcoma

The precise frequency of these tumors is difficult to estimate because they are excluded from some reports and included in others, and the terminology used has been inconsistent. In general, endometrial stromal sarcomas are thought to be the most frequently encountered stromal tumor variant and are twice as common as high-grade undifferentiated sarcomas.

Typically, they extensively invade the myometrium and extend to the serosa in approximately half of cases (Fig. 34-3). Less often, they present as a solitary, well-delineated, predominantly intramural mass that is difficult to grossly distinguish from an endometrial stromal nodule. Microscopically, endometrial stromal sarcomas resemble the stromal cells of proliferative-phase endometrium (Fig. 34-4) (Hoang, 2018).

Metastases are rarely detected prior to the diagnosis of the primary lesion. However, permeation of the lymphatic and vascular channels is characteristic. In up to one third of cases, extrauterine extension is present, often appearing as "worm-like" plugs of tumor within the vessels of the broad ligament and adnexa. At operation, this may resemble intravenous leiomyomatosis or a broad ligament leiomyoma, but frozen section analysis can usually make the distinction.

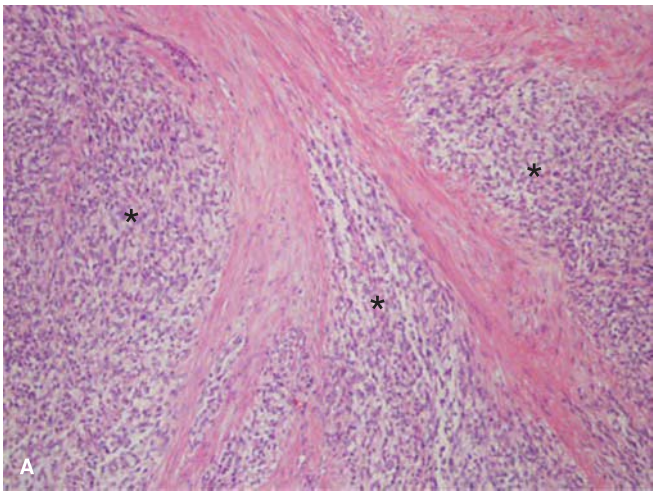
High-Grade Undifferentiated Sarcoma

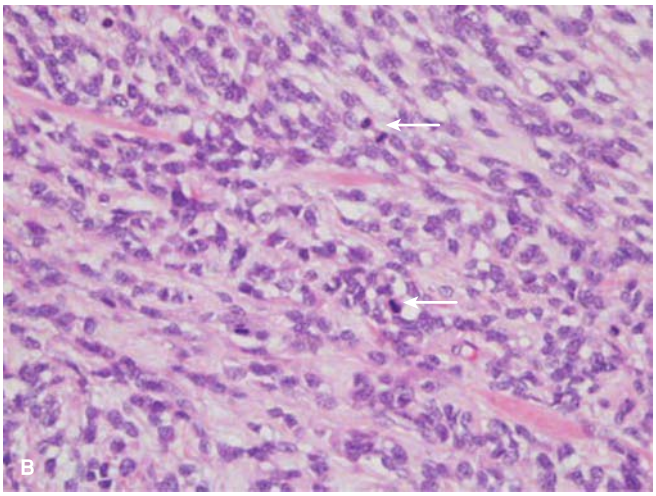
Compared with endometrial stromal sarcomas, these tumors tend to be larger and more polypoid, often filling the uterine cavity. Instead of an infiltrating pattern, high-grade undifferentiated sarcomas displace the myometrium more destructively, leading to prominent hemorrhage and necrosis.

Microscopically, the cells are larger and more pleomorphic. The presence of marked cellular atypia is characteristic. Typically, there are more than 10 mitoses per 10 high-power fields, but frequently more than 20 mitoses are seen in the most active areas. These tumors lack specific differentiation and bear no histologic resemblance to endometrial stroma (Oliva, 2014b; Zaloudek, 2011).

Adenosarcoma

This rare, biphasic neoplasm is characterized by a benign epithelial component and a sarcomatous mesenchymal component.





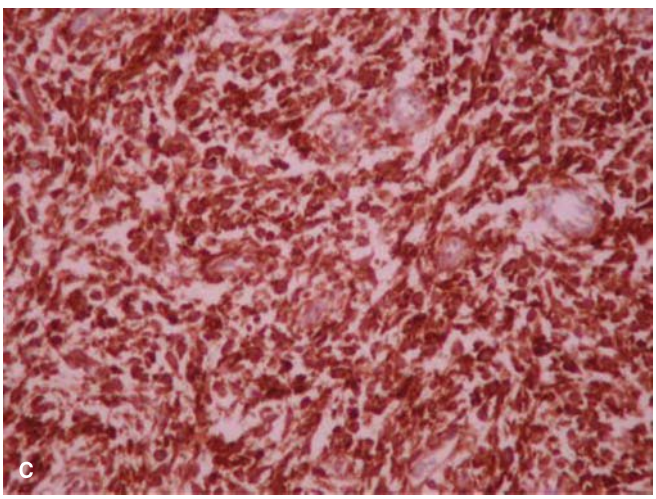


FIGURE 34-4 Endometrial stromal sarcoma (ESS). **A.** ESS is composed of cells morphologically similar to proliferative phase endometrial stromal cells. In this low-power view that involved the corpus and cervix, irregular tongues of tumor (*asterisks*) are seen dissecting into the cervical stroma. **B.** The tumor cells are spindled and relatively bland, similar to normal endometrial proliferative phase stroma. Two mitoses are identified in this single medium-power field (*white arrows*). **C.** Endometrial stroma marks positively with CD10, as does ESS. A battery of immunostains, including CD10, may be used to help distinguish ESS from other spindle cell neoplasms. (Reproduced with permission from Dr. Kelley Carrick.)

Tumors may develop in women of all ages. Grossly, adenosarcomas grow as exophytic polypoid masses that extend into the uterine cavity. Rarely, they may arise in the myometrium, presumably from adenomyosis. Microscopically, isolated glands are dispersed throughout the mesenchymal component and are often dilated or compressed into thin slits (Fig. 34-5). Typically, the mesenchymal component resembles an endometrial stromal sarcoma or fibrosarcoma and contains varying amounts of fibrous tissue and smooth muscle. In general, these are considered low-grade tumors with mild atypia and relatively few mitotic figures. However, 10 percent have a more malignant behavior due to one-sided proliferation of the sarcomatous, often high-grade, component. This subgroup of adenosarcomas is designated as having "sarcomatous overgrowth," and patients have a poor prognosis (Friedlander, 2014; Wells, 2014).

PATTERNS OF SPREAD

Uterine sarcomas generally fall into two categories of malignant behavior. Leiomyosarcomas and high-grade undifferentiated sarcomas are consistently characterized by an aggressive growth pattern and rapid disease progression despite treatment. In contrast, endometrial stromal sarcomas and most adenosarcomas have an indolent growth pattern with long disease-free intervals. All of these tumors invade, to some degree, by direct extension.

Leiomyosarcomas have a propensity for hematogenous dissemination. Lung metastases are particularly common, and more than half of patients will have distant spread if diagnosed with recurrent disease. In the absence of widespread disease, leiomyosarcomas rarely metastasize via lymphatic channels (Machida, 2017).

STAGING

Uterine sarcomas are surgically staged. Formerly, most clinicians used the FIGO surgical staging system for endometrial cancer to stage uterine sarcomas. Endometrial stromal sarcomas and adenosarcomas share new criteria, whereas leiomyosarcomas have a different system for stage I (Table 34-3 and Fig. 34-6). Stages I and II are considered early-stage disease, whereas stages III and IV reflect advanced disease.

TREATMENT OF EARLY-STAGE DISEASE

Surgery

The highest chance of cure is achieved by complete surgical resection of a sarcoma that is confined to the uterus (Seagle, 2017b). The staging laparotomy described for endometrial cancer in Chapter 33 (p. 712) can be revised to incorporate the unique spread patterns of uterine sarcomas. Exploration is particularly important to assess the abdomen for unresectable or widely metastatic disease that might indicate a need to abort the procedure. Some evidence shows benefit from aggressive cytoreductive surgery (Dinh, 2004; Leath, 2007; Thomas, 2009).

With *uterine leiomyosarcoma*, all patients should undergo a hysterectomy, if feasible. A modified radical or radical procedure may be occasionally required if there is parametrial infiltration. In

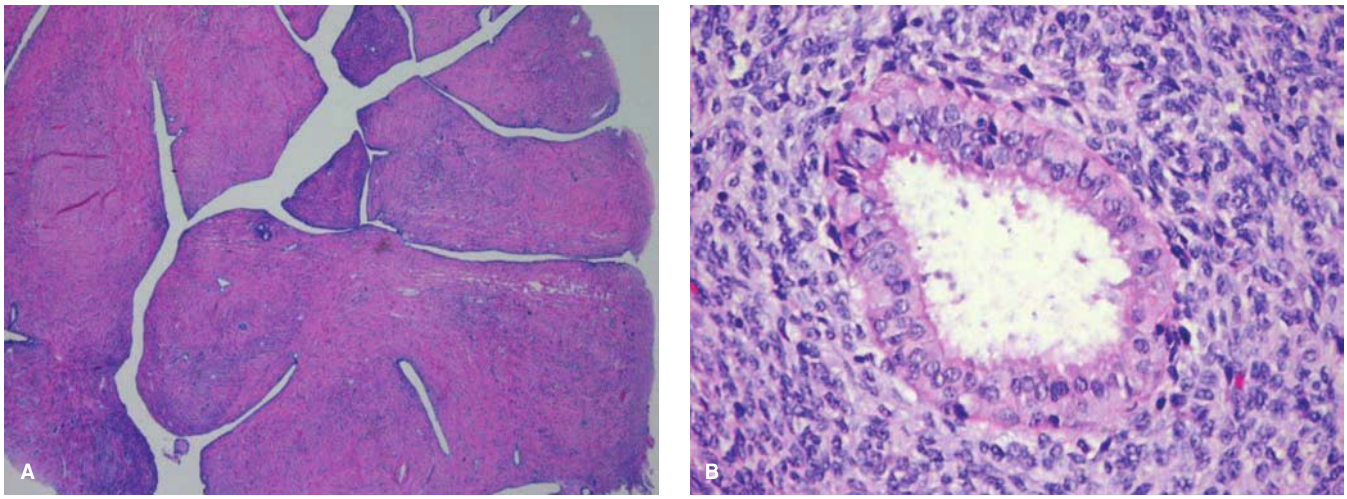

FIGURE 34-5 Adenosarcoma. **A.** A broad-based villous architecture is seen typically. **B.** Normal endometrial glands are surrounded by a cellular stroma consisting of a low-grade sarcoma. In this case, an endometrial stromal sarcoma is the sarcoma component. (Reproduced with permission from Dr. Raheela Ashfaq.)

TABLE 34-3. FIGO Staging for Uterine Sarcomas (Leiomyosarcomas, Endometrial Stromal Sarcomas, and Adenosarcomas)

Stage	Characteristics
Leiomyosarcomas	
I	**Tumor limited to uterus**
IA	<5 cm
IB	>5 cm
II	**Tumor extends to the pelvis**
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
III	**Tumor invades abdominal tissues (not just protruding into the abdomen)**
IIIA	One site
IIIB	>One site
IIIC	Metastasis to pelvic and/or paraaortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis
Adenosarcomas and endometrial stromal sarcomas[a]	
I	**Tumor limited to uterus**
IA	Tumor limited to endometrium/endocervix with no myometrial invasion
IB	Less than or equal to half myometrial invasion
IC	More than half myometrial invasion
II	**Tumor extends to the pelvis**
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
III	**Tumor invades abdominal tissues (not just protruding into the abdomen)**
IIIA	One site
IIIB	>One site
IIIC	Metastasis to pelvic and/or paraaortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

[a]Note: Simultaneous tumors of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors.
FIGO = International Federation of Gynecology and Obstetrics.

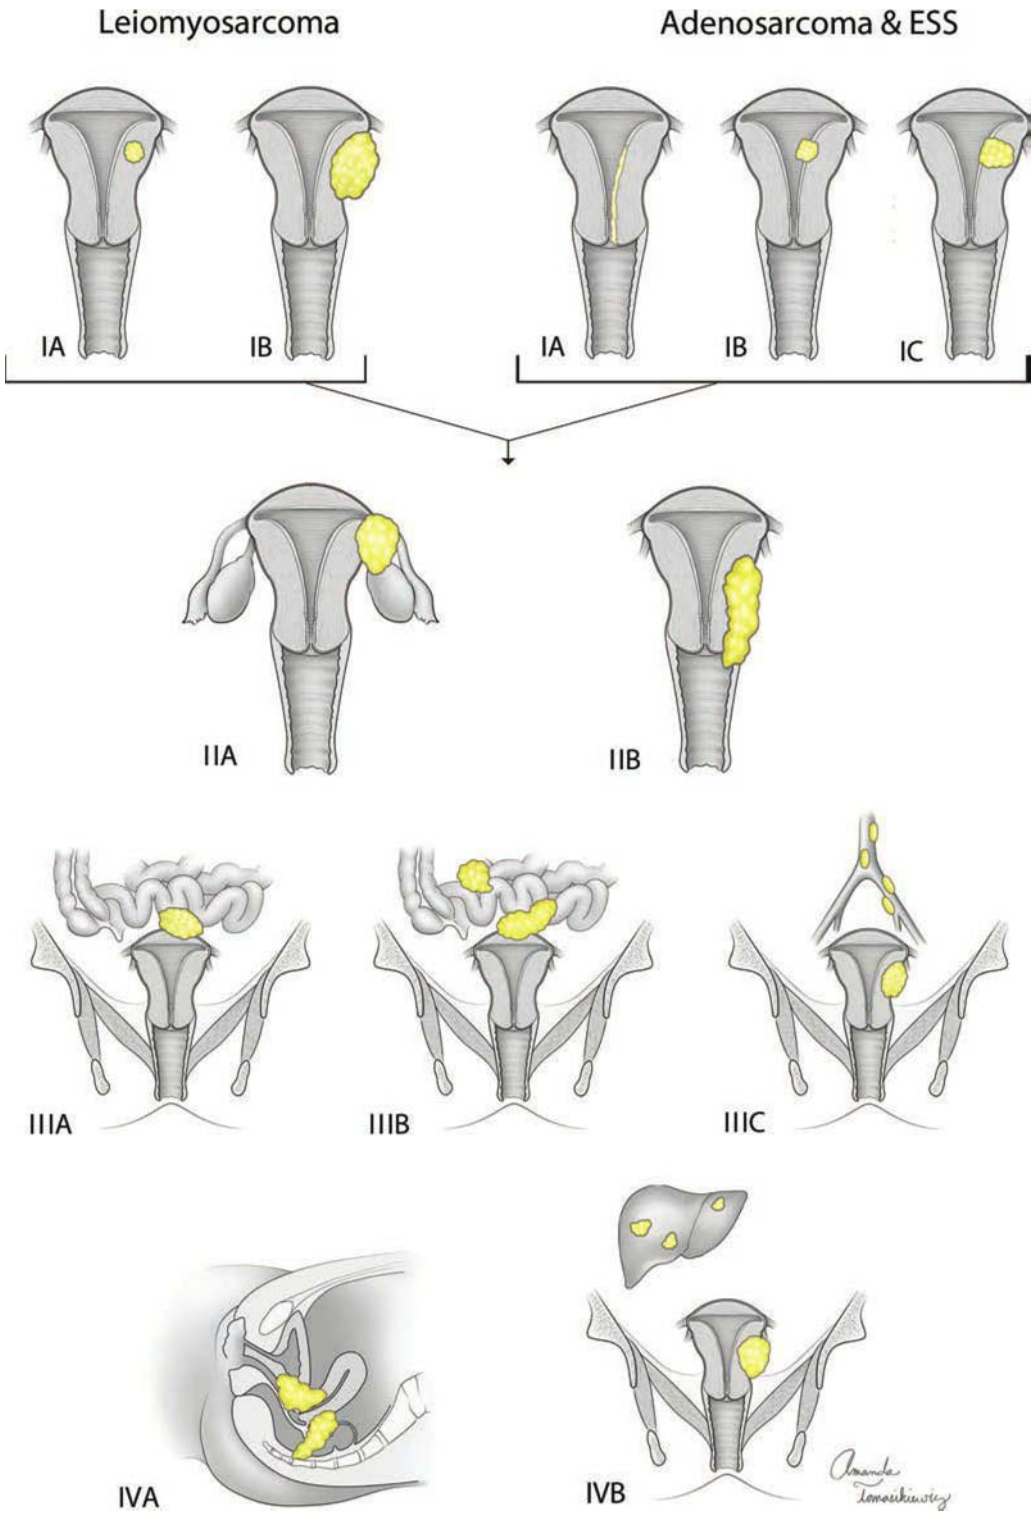

FIGURE 34-6 FIGO staging of leiomyosarcoma and that of adenosarcoma and endometrial stromal sarcoma (ESS).

the absence of other gross disease, fewer than 5 percent will have ovarian or nodal metastases. Ovarian preservation is therefore an option for premenopausal women (Seagle, 2017b). In addition, lymph node dissection is reserved for only patients with clinically suspicious nodes. For STUMP, hysterectomy alone is sufficient.

Endometrial stromal tumors and *adenosarcomas* also are best treated by hysterectomy (Seagle, 2016). Again, a more radical procedure may be required to encompass local disease. Preservation of the ovaries is generally accepted for adenosarcomas in the absence of extrauterine disease but may result in a higher recurrence rate for endometrial stroma sarcoma (Michener, 2001; Nasioudis, 2019). However, bilateral salpingo-oophorectomy (BSO) is indicated for high-grade undifferentiated sarcomas (Meurer, 2019). Unlike leiomyosarcoma, lymph node dissection is typically more informative. Although nodal metastases are most often identified in patients with obvious extrauterine disease, they do occur in 5 to

10 percent of patients with no evidence for intraabdominal spread (Machida, 2017; Seagle, 2017a).

Surveillance

In women with early-stage uterine sarcoma, adjuvant treatment is routinely employed but has not been demonstrated to improve survival rates (Hensley, 2018; Koh, 2018; Reed, 2008). Thus, because the recurrence rate for the clinically aggressive types is excessive, enrollment in an experimental clinical trial should be carefully considered, if available.

After surgery, menopausal symptoms such as hot flashes may be treated as appropriate for uterine leiomyosarcomas, high-grade undifferentiated sarcomas, and adenosarcomas. However, the use of estrogen replacement therapy for endometrial stromal sarcoma has been associated with disease progression and is avoided (Chu, 2003; Nasioudis, 2019; Pink, 2006).

Surgically treated patients with uterine sarcoma should have a physical examination every 3 months for the first 2 years and then at 6- to 12-month intervals thereafter. Due to the high rates of distant recurrences, CT scanning of the chest, abdomen, and pelvis are recommended at 6- to 12-month intervals or as clinically indicated (Salani, 2017). Most recurrences will be distant, and thus Pap tests are largely irrelevant.

Adjuvant Radiation

Approximately half of patients with stage I disease who are observed without adjuvant therapy will relapse (Leath, 2009). Due to the rarity of these tumors and limited data to support a consistent approach, the use of postoperative therapy is usually individualized. From a prospective trial that randomly assigned 224 women over 13 years with all subtypes of surgical stage I or II uterine sarcomas to either pelvic radiation or no further treatment, no benefit was found for those with leiomyosarcomas. Unfortunately, the number of patients with endometrial stromal sarcoma was too small to permit analysis (Reed, 2008).

Adjuvant Chemotherapy

There is yet no proven survival benefit for using adjuvant chemotherapy in patients with stage I uterine sarcoma (Hensley, 2018; Rauh-Hain, 2014). For leiomyosarcomas, completely resected stage I and II disease treated with gemcitabine and docetaxel was not associated with significantly improved disease-free or overall survival rates (Hensley, 2018; Littell, 2017). In high-grade undifferentiated sarcomas, chemotherapy regimens used for more advanced disease may be considered. For stages I and II endometrial stromal sarcoma and adenosarcoma, observation is recommended (Koh, 2018). However, because most patients will recur distantly, adjuvant systemic treatment is frequently used for recurrences.

Fertility-Sparing Management

Rarely, young patients may desire to delay definitive hysterectomy after a fertility-sparing "myomectomy" demonstrates sarcomatous features on final pathology (Lissoni, 1998; Yan, 2010). Expectant management following tumor resection can result in successful pregnancies in select patients. However, it is risky not to perform a hysterectomy, and eventually all such women should undergo this surgery. Most patients, even those with negative margins, are counseled regarding definitive surgery and ovarian preservation during surgery for clinical stage I uterine leiomyosarcomas or endometrial stromal sarcomas. Egg retrieval, assisted reproductive technologies, and pregnancy surrogacy would still be possible. For more advanced disease, fertility-sparing management is not a reasonable option.

TREATMENT OF ADVANCED OR RECURRENT DISEASE

Patients with advanced or recurrent uterine sarcoma generally have a dismal prognosis. For advanced-stage disease, upfront surgery with maximal effort to completely remove all visible disease (similar in approach to advanced ovarian cancer) is considered standard. This is generally followed by adjuvant chemotherapy. Neoadjuvant chemotherapy can be considered for patients whose disease is considered unresectable or who are medically unfit for surgery.

For recurrent disease, secondary cytoreductive surgery may be feasible in some circumstances (Giuntoli, 2007). Palliative radiation also may have a role, depending on the site and distribution of the tumor. In general, uterine sarcomas have a propensity for relapse at distant sites, and chemotherapy is more useful. Since current treatment options have only modest efficacy, patients are encouraged to enroll in experimental clinical trials.

Leiomyosarcoma

Doxorubicin is considered the most active single agent (Miller, 2000; Omura, 1983). However, treatment with the combination of gemcitabine and docetaxel currently has the highest proven response rate (36 percent) (Hensley, 2008). Addition of bevacizumab to this regimen was not beneficial (Hensley, 2015). Other agents are approved for leiomyosarcoma refractory to doxorubicin and include trabectedin, dacarbazine, temozolomide, and pazopanib. Response rates are generally less than 20 percent, and clinical trial participation is encouraged.

For late recurrences of leiomyosarcoma, consideration of surgery must be individualized. Five-year survival rates of 30 to 50 percent have been reported following pulmonary resection for lung metastases. Local and regional recurrences also may be amenable to surgical resection (Giuntoli, 2007).

Endometrial Stromal Tumors

Surgical resection may be feasible for some patients with recurrent endometrial stromal sarcoma, but hormonal therapy is particularly useful. In general, these tumors are estrogen- and progesterone-receptor (ER/PR) positive (Sutton, 1986). Progestins such as megestrol acetate and medroxyprogesterone acetate are most commonly used either postoperatively for advanced-stage disease or for relapses (Reich, 2006). Using this strategy, complete responses are often possible. Aromatase inhibitors and gonadotropin-releasing hormone (GnRH) agonists also have demonstrated activity (Burke, 2004; Leunen, 2004).

High-grade undifferentiated sarcomas do not exhibit the same level of sensitivity to hormonal agents, primarily because

TABLE 34-4. Overall Survival Rates of Women with Uterine Sarcomas (All Stages)

Type	5-Year Survival
Leiomyosarcoma	41%
Endometrial stromal tumors	
Endometrial stromal sarcoma	91%
High-grade undifferentiated sarcoma	33%
Müllerian adenosarcoma	72%

Data from Seagle, 2016; 2017a,b.

they are usually ER/PR negative. Advanced disease or recurrences of these rare tumors are also typically not amenable to surgical resection. Palliative radiation may have some utility. Systemic chemotherapy is usually the only option, and treatment decisions are often extrapolated from leiomyosarcoma studies.

SURVIVAL AND PROGNOSTIC FACTORS

In general, women with uterine sarcoma have a poor prognosis (Table 34-4). FIGO stage is the most important independent variable associated with survival (Livi, 2003). Other poor prognostic factors across all subtypes include older age, African-American race, and lack of primary surgery (Chan, 2008; Kapp, 2008; Nemani, 2008).

Tumor histology is the other main predictor of outcome. High-grade undifferentiated uterine sarcomas have the worst prognosis and are followed by the group of leiomyosarcomas (Seagle, 2017a,b). Endometrial stromal sarcomas and uterine adenosarcomas without sarcomatous overgrowth are the two notable exceptions. Patients with these tumors tend to have a good prognosis due to their indolent growth (Seagle, 2016, 2017a).

In the United States, ovarian cancer accounts for more deaths than any other gynecologic malignancy. Worldwide each year, more than 295,000 women are diagnosed, and 185,000 women die from this disease (Bray, 2018). Of these, epithelial ovarian carcinomas make up 90 percent of all cases, including the more indolent low-malignant-potential (borderline) tumors (Torre, 2018). The remainder includes germ cell and sex cord–stromal tumors, which are described in Chapter 36 (p. 756). Due to the similarities of primary peritoneal carcinomas and fallopian tube cancers, they are included within this section for simplicity.

Approximately one quarter of patients will have stage I disease and an excellent long-term survival rate. However, no test effectively screens for ovarian cancer, and early symptoms are few. As a result, two thirds of patients have advanced disease when diagnosed. Debulking surgery sequenced with platinum-based chemotherapy usually results in clinical remission. However, up to 90 percent of these women will develop a relapse that eventually leads to disease progression and death.

EPIDEMIOLOGY AND RISK FACTORS

In the United States, 1 in 78 women (1.3 percent) will develop ovarian cancer during her lifetime (Torre, 2018). Because the incidence has declined by 30 percent during the past three decades, ovarian cancer no longer resides among the top ten leading causes of cancer in women. In 2019, 22,530 new cases and 13,980 deaths are expected. Yet due to the high rate of mortality, ovarian cancer remains the fifth leading cause of cancer-related death (Siegel, 2019). Overall, the average age at diagnosis is in the early 60s.

Numerous reproductive, environmental, and genetic risk factors have been associated with ovarian cancer (Table 35-1) (Armstrong, 2019). The most important is a *family history* of breast or ovarian cancer, and up to 25 percent of patients have an inherited genetic predisposition (American College of Obstetricians and Gynecologists, 2017a). For the other 75 percent with no identifiable genetic link for their ovarian cancer, risks have traditionally been attributed to a pattern of uninterrupted ovulatory cycles during the reproductive years (Pelucchi, 2007). Repeated stimulation of the ovarian surface epithelium is hypothesized to lead to malignant transformation (Schildkraut, 1997).

Nulliparity is associated with long periods of repetitive ovulation, and patients without children have double the risk of developing ovarian cancer (Purdie, 2003). Among nulliparas, those with a history of infertility have an even higher risk. This association is thought to reflect an inherent ovarian predisposition rather than an iatrogenic effect of ovulation-inducing drugs. For example, women treated for infertility who successfully

TABLE 35-1. Risk Factors for Developing Epithelial Ovarian Cancer

Nulliparity
Early menarche
Late menopause
White race
Increasing age
Residence in North America and Northern Europe
Family history
Personal history of breast cancer
Ethnic background (European Jewish, Icelandic, Hungarian)
Postmenopausal hormone therapy
Pelvic inflammatory disease

Modified from Schorge, 2010, with permission.

achieve a live birth do not have a greater risk of ovarian cancer (Rossing, 2004). For all women, risks decrease with each live birth, eventually plateauing in women delivering five times (Hinkula, 2006).

Early menarche and *late menopause* also are associated risks. In contrast, breastfeeding has a protective effect, perhaps by prolonging anovulation (Yen, 2003). Presumably by also preventing ovulation, long-term combination oral contraceptive (COC) use reduces the risk of ovarian cancer by up to 50 percent. The duration of protection persists for more than 30 years after the last use (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008). In contrast, hormone replacement therapy after menopause carries an elevated associated risk (Lee, 2016).

White women have the highest incidence of ovarian cancer among all racial and ethnic groups. Compared with that of black and Hispanic women, the risk is elevated by 30 to 40 percent (Torre, 2018). Racial discrepancies in parity and rates of gynecologic surgery are believed to account for some of the differences.

Tubal ligation and *hysterectomy* are each associated with a substantial reduction in risk (Rice, 2014). Theoretically, any gynecologic procedure that precludes irritants from reaching the ovaries via ascension from the lower genital tract might plausibly exert a similar protective effect. In turn, women who regularly use perineal talc may possibly have an increased risk (Cramer, 2016; Penninkilampi, 2018).

Women *residing in North America*, *Northern or Eastern Europe*, or *any industrialized Western country* have a higher ovarian cancer risk. Globally, the incidence varies greatly, but developing countries have approximately half the rate (Torre, 2015, 2017). Regional dietary habits may be partly responsible (Kiani, 2006). For example, consumption of foods low in fat but high in fiber, carotene, and vitamins appears protective (Zhang, 2004).

Most epithelial ovarian cancers are now believed to actually originate in the fallopian tube fimbria. This recognition makes it difficult to reconcile these listed risk factors and current theories of carcinogenesis (American College of Obstetricians and Gynecologists, 2019). New biologically plausible theories will be required.

Hereditary Breast and Ovarian Cancer

Genetic Screening

A family history of ovarian cancer in a first-degree relative, that is, a mother, daughter, or sister, triples a woman's lifetime risk. Two or more afflicted first-degree relatives or other individuals with premenopausal breast cancer further escalate risk. Approximately 75 percent of inherited ovarian cancers result from germline mutations in the *BRCA1*, *BRCA2*, or other homologous recombination deficiency genes. Thus, any patient with a personal history of epithelial ovarian cancer or breast cancer in certain circumstances or those from a family carrying a known deleterious mutation should undergo testing (Table 35-2) (Lancaster, 2015).

If a family history is mainly composed of colon cancer, clinicians may consider Lynch syndrome, also known as *hereditary nonpolyposis colorectal cancer (HNPCC)*. Patients with this syndrome have a high lifetime risk of colon cancer (85 percent) and ovarian cancer (10 to 12 percent). Endometrial cancer is the predominant gynecologic malignancy, and women with the syndrome have a 40 to 60 percent lifetime risk for this cancer. HNPCC is described in more detail in the endometrial cancer chapter (Chap. 33, p. 700).

Typically, an individual is referred to a certified genetic counselor, and a comprehensive pedigree is constructed first. Then, risk assessment is performed using one of several validated population models. These include the BRCAPRO and Tyrer-Cuzick programs, which are available, respectively, at http://www4.utsouthwestern.edu/breasthealth/cagene/ and by contacting the International Breast Cancer Intervention Study (IBIS) at ibis@cancer.org.uk. These models and their associated software quantify an individual's risk for carrying a germline deleterious mutation.

TABLE 35-2. Women Who Should Undergo Genetic Testing

Epithelial ovarian cancer[a] at any age
Breast cancer diagnosed at age 45 or younger
Breast cancer with two distinct and sequential primaries, first one diagnosed at age 50 or younger
Breast cancer that is triple-negative and diagnosed at age 60 or younger
Breast cancer at any age, with at least one close relative[b] diagnosed at age 50 or younger
Breast cancer diagnosed at any age, with two or more close relatives with breast cancer; one close relative with epithelial ovarian cancer; or two close relatives with pancreatic cancer or aggressive prostate cancer
Breast cancer, with a close male relative with breast cancer at any age
Breast cancer and Ashkenazi Jewish ancestry
Individuals from a family with a known deleterious mutation (see Table 35-3)

[a]Throughout table, peritoneal and fallopian tube cancer are considered as part of the spectrum of the Hereditary Breast/Ovarian Cancer syndrome.
[b]Throughout table, *close relative* is defined as a first-, second-, or third-degree relative (i.e., mother, sister, daughter, aunt, niece, grandmother, granddaughter, first cousin, great grandmother, great aunt).
Adapted from Lancaster, 2015 with permission.

BRCA1 and *BRCA2* Genes

These are tumor-suppressor genes whose protein products are BRCA1 and BRCA2. These two proteins provide double-stranded DNA repair through the process of *homologous recombination (HR)* to preserve intact chromosomal structure. Mutations of *BRCA1* and *BRCA2* genes lead to BRCA1 and BRCA2 protein dysfunction, which results in genetic instability and subjects cells to a higher risk of malignant transformation.

The *BRCA1* gene is located on chromosome 17q21. Patients with a proven mutation have a dramatically elevated risk of developing ovarian cancer (39 to 46 percent). *BRCA2* is located on chromosome 13q12 and in general is less likely to lead to ovarian cancer (10 to 27 percent). The estimated lifetime risk of breast cancer with a *BRCA1* or *BRCA2* mutation is 45 to 85 percent (American College of Obstetricians and Gynecologists, 2017a).

Until recently, it was thought that HR was performed almost exclusively by the *BRCA1* and *BRCA2* genes. Instead, up to one quarter of predisposing germline mutations is due to another of the HR deficiency genes (Table 35-3) (American College of Obstetricians and Gynecologists, 2017a; Ring, 2017). All of these genes are inherited in an autosomal dominant fashion but show variable penetrance. Thus, although a carrier will pass the gene to a son or daughter in 50 percent of cases, the offspring with the gene mutation may or may not actually develop breast or ovarian cancer. As a result, *BRCA1* or *BRCA2* or other HR deficiency gene mutations can appear to skip generations.

Genetic Testing

The two main genetic testing options for hereditary breast and ovarian cancer syndrome are *BRCA* mutation testing or multigene panel testing that includes *BRCA* and other genetic mutations. The choice of testing strategy will depend on whether or

TABLE 35-3. Genes Associated with Breast or Ovarian Cancer

Genetic Syndrome	Gene	Breast Cancer Risk[a]	Ovary Cancer Risk[a,b]	Other Cancer Risk	Risk-Reduction Strategy (age to consider)
HBOC	*BRCA1*	↑	↑	Prostate	RRSO (35–40 y)
HBOC	*BRCA2*	↑	↑	Melanoma, pancreas, prostate	RRSO (40–45 y)
Lynch	*MLH1*, *MSH2*, *EPCAM*, *MSH6*, *PMS2*	?	↑	Uterus, colon, renal pelvis, small bowel + others	RRSO after childbearing (35–40 y) Risk-reducing hysterectomy after childbearing
HOC	*BRIP1*	—	↑	?	Consider RRSO (45–50 y)
HOC	*RAD51C*	—	↑	?	Consider RRSO (45–50 y)
HOC	*RAD51D*	—	↑	?	Consider RRSO (45–50 y)
Peutz-Jeghers	*STK11*	↑	↑ SCST	Colorectal, stomach, small bowel, pancreas	No recommendations
Cowden	*PTEN*	↑	—	Uterus, thyroid, renal, colorectal	Discuss hysterectomy after childbearing
Li-Fraumeni	*TP53*	↑	—	Sarcomas, brain, leukemia, medulloblastoma, adrenocortical	No recommendations
Ataxia-telangiectasia	*ATM*	↑	—	—	No recommendations
Hereditary diffuse gastric cancer	*CDH1*	↑	—	Stomach	No recommendations
_____	*CHEK2*	↑	—	Colon	No recommendations
_____	*PALB2*	↑	—	?	No recommendations

[a]Legend: ↑ = increased risk; — = no increased risk; ? = insufficient evidence or unknown.
[b]Includes fallopian tube and primary peritoneal cancers.
HBOC = hereditary breast and ovarian cancer; HOC = hereditary ovarian cancer; RRSO = risk-reducing salpingo-oophorectomy; SCST = sex cord–stromal tumor.

not a specific mutation is known within the family (American College of Obstetricians and Gynecologists, 2017a). Ideally, genetic testing identifies women with deleterious mutations, leads to intervention with prophylactic surgery, and thereby prevents ovarian cancer.

Four distinct results are possible with this testing. A "true positive" test suggests the presence of a deleterious mutation. The most common are 185delAG or 5382insC in *BRCA1* and 6174delT in *BRCA2*. Each of these "frameshift" mutations significantly alters the downstream amino acid sequence, resulting in an altered BRCA1 or BRCA2 tumor suppressor protein.

Second, "variants of uncertain clinical significance" may actually be pathogenic (true mutations) or just polymorphisms (normal variants found in at least 1 percent of alleles in the general population). These unclassified variants are common, representing approximately one third of *BRCA1* test results and half of those for *BRCA2*. Most are missense mutations, which result in a single amino acid change in the protein but without a frameshift. Given the prognostic uncertainty and high rate of reclassification, individualized counseling and directing efforts toward surveillance, chemoprevention, or salpingectomy are recommended (Garcia, 2014).

The third potential and most reassuring genetic test result is "true negative." This indicates the absence of a deleterious mutation in an individual who has relatives with cancer and a known pathogenic variant in the family.

The fourth possible outcome is "uninformative negative," which indicates the absence of a deleterious mutation in an individual. However the test is inconclusive because other cancer-affected family members have not tested positive for the given mutation. In this case, the affected family members may have no high-risk mutation or it may be undetectable (American College of Obstetricians and Gynecologists, 2017a). For example, due to the large size of the *BRCA1* and *BRCA2* genes, the false-negative rate is 5 to 10 percent. To capture additional, otherwise undetected large genomic rearrangements in *BRCA* and to expand the testing for other HR deficiency genes, individuals with a negative test result 5 to 10 years ago might need to be retested.

PREVENTION

Ovarian Cancer Screening

In addition to genetic testing, other screening strategies for ovarian cancer have been evaluated. However, despite enormous effort, no evidence suggests that routine screening with serum markers, sonography, or pelvic examinations lowers mortality rates. Hundreds of possible markers have been identified, yet no test currently available approaches sufficient levels of accuracy (American College of Obstetricians and Gynecologists, 2017b). Consequently, the U.S. Preventive Services Task Force (2018) recommends against screening in asymptomatic women who are not known to have a high-risk inherited syndrome.

High-Risk Women

Screening strategies are mainly directed at *BRCA1* or *BRCA2* carriers and women with a strong family history of breast and ovarian cancer. Even so, cancer antigen 125 (CA125) serum level measurements and/or transvaginal sonography are not routinely recommended. An exception is their use in women at high-risk for short-term surveillance starting at age 30 to 35 years and continuing until risk-reducing surgery (American College of Obstetricians and Gynecologists, 2017a).

CA125 is a glycoprotein that is not produced by normal ovarian epithelium but that may be produced by both benign and malignant ovarian tumors. CA125 is synthesized within affected ovarian epithelial cells and often secreted into cysts. In benign tumors, excess antigen is released into and may accumulate within cyst fluid. Hypothetically, the abnormal tissue architecture associated with malignant tumors allows antigen release into the vascular circulation (Verheijen, 1999).

Alone, CA125 is a poor marker for ovarian cancer detection. However, a more sensitive *R*isk of *O*varian *C*ancer *A*lgorithm (ROCA) is based on the slope of serial CA125 measurements drawn at regular intervals (Skates, 2003). If a ROCA score exceeds a 1-percent risk of having ovarian cancer, patients then undergo transvaginal sonography to determine whether additional intervention is warranted. This strategy, in 3692 high-risk women, demonstrated somewhat better ability to detect ovarian cancer at an early stage. However, it still was deemed not very clinically useful (Skates, 2017).

General Population

To establish the effect of ROCA-based CA125 screening and study-directed sonography, a randomized trial of 202,638 patients was conducted. In The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), asymptomatic, average-risk postmenopausal women aged 50 to 74 years were randomly assigned to no treatment, to annual CA125 screening with transvaginal sonography as a second-line test if indicated by ROCA interpretation, or to annual screening with transvaginal sonography. The ROCA-directed approach demonstrated a 35-percent positive predictive value, more than 10 times higher than annual sonography (3 percent). Although ROCA-directed sonography was shown to be feasible in this study, the mortality rate reduction was not significant (Jacobs, 2016). Because no sufficiently accurate early detection tests are currently available, routine screening for women at average risk is not recommended (U.S. Preventive Services Task Force, 2018).

Physical Examination

In general, pelvic examination only occasionally detects ovarian cancer, generally when the disease is already in advanced stages. In asymptomatic women, there is no evidence that it lowers mortality or morbidity rates as a screening test (Bloomfield, 2014; U.S. Preventive Services Task Force, 2017).

Chemoprevention

Noted on page 733, COC use is associated with an up to 50-percent decreased risk of developing ovarian cancer. More than 200,000 cases of this cancer and 100,000 deaths are estimated to have been prevented by COC use (Collaborative Group on Epidemiological Studies of Ovarian Cancer, 2008). Emerging evidence suggests that intrauterine devices also may reduce

the risk (Jareid, 2018). Discussed in Chapter 5 (p. 126), the slightly higher risk of breast cancer during current COC use should be presented during patient counseling (Mørch, 2017).

COCs are suitable for women with a high-risk inherited syndrome and similarly can lower later ovarian cancer rates (Friebel, 2014). Rates of breast cancer linked to COC use do not appear elevated in this group (Iodice, 2010; Moorman, 2013).

Prophylactic Surgery

The only proven way to directly prevent ovarian cancer is surgical removal. However, premenopausal oophorectomy has several negative health consequences (Chap. 43, p. 957). Moreover, with growing recognition that carcinogenesis actually originates on the fallopian tube fimbria, consideration of opportunistic salpingectomy at the time of gynecologic surgery or in place of tubal ligation has revolutionized the approach to risk-reduction in the general population (American College of Obstetricians and Gynecologists, 2019).

In women at high risk of ovarian cancer from known mutations, bilateral salpingectomy alone is not currently recommended for ovarian cancer risk reduction. However, clinical trials are underway to determine whether prophylactic salpingectomy–delayed oophorectomy (PSDO) is an effective strategy. Currently, in these high-risk women, prophylactic bilateral salpingo-oophorectomy (BSO) still is recommended.

The procedure's timing can be individualized depending on the particular genetic mutation, the patient's desires for further childbearing, and her family history. In general, prophylactic BSO should be offered to *BRCA1* carriers at age 35 to 40 years. For *BRCA2* carriers, BSO is recommended between 40 and 45, and at age 45 to 50 years for other HR deficiency (*BRIP1*, *RAD51C*) carriers (American College of Obstetricians and Gynecologists, 2017a).

In these patients, the procedure is approximately 90-percent effective in preventing epithelial ovarian cancer (Kauff, 2002; Rebbeck, 2002). Prophylactic BSO also reduces the risk of developing breast cancer by 50 percent (Rebbeck, 2002). Predictably, the protective effect is strongest among premenopausal women (Kramer, 2005). In women with HNPCC, the ovarian cancer risk reduction approaches 100 percent (Schmeler, 2006).

The term *prophylactic* implies that the tubes and ovaries are normal at the time of removal. However, approximately 5 percent of *BRCA* mutation carriers undergoing prophylactic BSO will have an otherwise undetected, often microscopic, fallopian tube cancer at the time of surgery (Manchanda, 2011; Sherman, 2014). To account for this possibility, cytologic washings should be collected during surgery. Peritoneal surfaces are thoroughly inspected, and abnormal areas are biopsied. Last, the pathology requisition should clearly state that the BSO was performed for a prophylactic indication. In these cases, the ovaries and tubes, especially the fimbria, undergo more intensive scrutiny and are serially microsectioned to identify occult disease. Using a rigorous operative and pathologic protocol such as this can significantly raise the detection rate of occult tubal or ovarian malignancy in carriers of *BRCA* mutations (American College of Obstetricians and Gynecologists, 2017a). Typically, the BSO, washings collection, and peritoneal biopsy can be completed laparoscopically.

Prophylactic BSO in young women will induce premature menopause and its associated vasomotor and urogenital symptoms, decline in sexual interest, and osteoporosis. Estrogen therapy (ET) commonly is used to alleviate these symptoms in women without prior breast cancer (American College of Obstetricians and Gynecologists, 2019). Other ET contraindications and options are found in Chapter 22 (p. 480) Overall, mainly due to the favorable reduction in cancer worries, prophylactic BSO does not adversely affect quality of life (Madalinska, 2005).

In women with HNPCC syndrome, hysterectomy is mandatory when performing prophylactic BSO because of coexisting endometrial cancer risks. In *BRCA* mutation carriers, hysterectomy should not be recommended routinely (Vyarvelska, 2014). Few reports have suggested a meaningful association between *BRCA* mutations and a greater risk of endometrial cancer. Mainly, these develop in patients taking tamoxifen for breast cancer treatment or for breast cancer chemoprevention (Beiner, 2007).

In low-risk patients who are not *BRCA* carriers, risk-reducing salpingectomy also is now considered in those undergoing hysterectomy or permanent sterilization. Ovarian cancer risk is reduced up to 65 percent (Falconer, 2015; Lessard-Anderson, 2014). This consideration has been endorsed by both the Society of Gynecologic Oncology (Walker, 2015) and the American College of Obstetricians and Gynecologists (2019). Pathologic specimen processing in low-risk women includes representative sections of the tube, any suspicious lesions, and entire sectioning of the fimbriae. Neither organization specifies pelvic washing collection in this low-risk population.

LOW-MALIGNANT-POTENTIAL TUMORS

Pathology

Ten to 15 percent of epithelial ovarian cancers have histologic and biologic features that are intermediate between clearly benign cysts and frankly invasive carcinomas. In general, these low-malignant-potential (LMP) tumors, also termed *borderline tumors*, are associated with risk factors that are similar to those for epithelial ovarian cancer (Huusom, 2006). Typically, they are not considered part of any of the hereditary breast-ovarian cancer syndromes. Although LMP tumors may develop at any age, on average, patients are in their mid-40s, which is 15 years younger than women with invasive ovarian carcinoma. For various reasons, their diagnosis and optimal management are frequently problematic.

Histologically, LMP tumors are distinguished from benign cysts by having at least two of the following features: nuclear atypia, epithelial stratification, microscopic papillary projections, cellular pleomorphism, or mitotic activity (Fig. 35-1). Unlike invasive carcinomas, LMP tumors lack stromal invasion. However, up to 10 percent of LMP tumors will exhibit areas of *microinvasion*, defined as foci measuring <3 mm in diameter and forming <5 percent of the tumor (Buttin, 2002). Due to the subtle nature of many of these findings, it is challenging to diagnose an LMP tumor with certainty based on intraoperative frozen section specimen analysis.

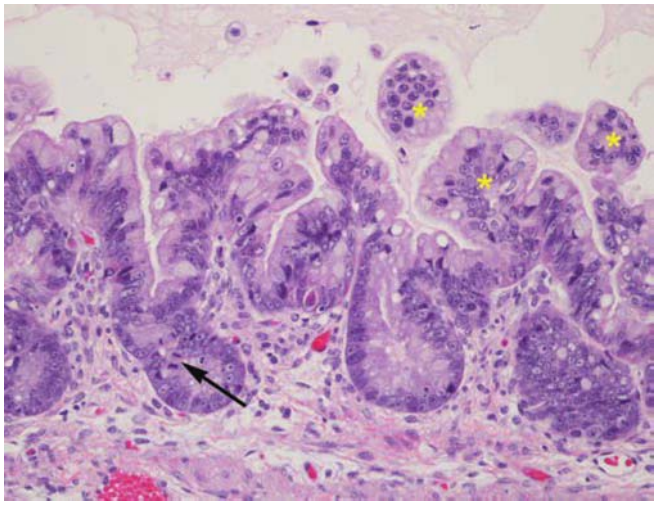

FIGURE 35-1 Mucinous borderline tumor/atypical proliferative mucinous tumor. These tumors are distinguished from benign mucinous cystadenomas by epithelial proliferation and nuclear atypia. This example of a mucinous borderline tumor has mild to moderate nuclear atypia as evidenced by limited nuclear pleomorphism and visible nucleoli. A mitotic figure also is seen (*arrow*). Epithelial proliferation is indicated by epithelial tufts (*asterisks*), which are unsupported by fibrovascular cores. (Reproduced with permission from Dr. Kelley Carrick.)

Clinical Features

Ovarian LMP tumors present similar to other adnexal masses. Preoperatively, no sonographic findings are pathognomonic, and serum CA125 levels are nonspecific. Depending on the clinical setting, computed tomography (CT) scanning may be indicated to exclude ascites or omental caking, which would suggest a more typical ovarian cancer. Regardless, any woman with a suspicious adnexal mass should have it removed.

Treatment

LMP tumors are primarily managed surgically. The operative plan will vary, depending on circumstances, and patients are carefully counseled beforehand. All women should be prepared for complete ovarian cancer surgical staging or debulking, if necessary. In many cases, a laparoscopic approach is appropriate. If laparotomy is planned, a vertical incision is selected to allow access to the upper abdomen and paraaortic nodes, if needed, for cancer staging.

During surgery, peritoneal washings are immediately collected upon entrance into the abdomen, which is then carefully explored. The ovarian mass is removed intact and submitted for pathologic consultation and frozen section evaluation. However, differentiating a benign adnexal mass, LMP tumor, or invasive ovarian cancer is almost impossible until final histologic slides have been reviewed (Shah, 2019). Accordingly, premenopausal women who have not completed childbearing and who are intraoperatively diagnosed with an LMP tumor may undergo fertility-sparing surgery. This approach preserves the uterus and contralateral ovary (Delle Marchette, 2019). This is a reasonable approach even if the final diagnosis shows invasive stage I cancer (Fruscio, 2016). Alternatively, postmenopausal women should undergo hysterectomy and BSO.

Biopsies of the peritoneum and omentum as a part of limited ovarian cancer staging are considered. However, they rarely contain microscopic foci of metastatic LMP tumor unless the tissues appear abnormal (Kristensen, 2014). Additionally, the appendix also is examined and potentially removed, especially if the tumor has mucinous histology (Timofeev, 2010). Without enlarged lymph nodes or a frozen section suggestive of frankly invasive disease, routine pelvic and paraaortic lymph node dissection may not be necessary (Rao, 2004).

LMP tumors are staged with the same FIGO criteria used for invasive ovarian cancer (p. 747). For the most part, surgical staging has limited value in altering the prognosis of those with LMP tumors unless invasive cancer is ultimately diagnosed (Wingo, 2006). Although 97 percent of gynecologic oncologists advocate comprehensive surgical staging of LMP tumors, in current practice it is performed in only 12 percent of patients (Lin, 1999; Menzin, 2000). This disparity stems from the fact that often the diagnosis is not suspected intraoperatively, no frozen section is requested or it is inaccurate, and a clinician is alerted only when the final pathology report has been completed. In this circumstance, consultation with a gynecologic oncologist is recommended, but comprehensive surgical restaging is not necessarily required if the tumor appears confined to a single ovary (Zapardiel, 2010). However, if a cystectomy has been performed, the risk of residual disease should prompt a discussion regarding removal of the entire adnexa with washings and limited staging (Poncelet, 2006).

For patients with stage II–IV disease, usually demonstrated by noninvasive implants (Fig. 35-2) or nodal metastases, the utility of adjuvant chemotherapy is speculative (Shih, 2010; Sutton, 1991). The most worrisome finding is invasive peritoneal or omental implants. In general, these patients are treated like those with typical epithelial ovarian carcinoma and receive surgical debulking and postoperative chemotherapy (Leary, 2014).

Prognosis

The prognosis is excellent for patients with ovarian LMP tumors. Five-year survival rates range from 96 to 99 percent for stages I–III, whereas it reaches 77 percent for stage IV disease (Trimble, 2002). Overall, more than 80 percent have stage I disease. If treated by hysterectomy and BSO, stage I tumors rarely, if ever, recur (du Bois, 2013). In fact, such women have an overall survival rate similar to the general population (Hannibal, 2014). Fertility-sparing surgery is associated with up to a 15-percent risk of relapse, usually in the contralateral ovary, but remains highly curable by reoperation and resection (Park, 2009; Rao, 2005).

Approximately 15 percent of women with LMP tumors have stage II and III disease, which almost invariably is serous histology. Stage IV ovarian LMP tumors account for fewer than 5 percent of diagnoses and have the worst prognosis (Trimble, 2002). For these advanced-stage tumors, the most reliable prognostic indicators are the presence of invasive peritoneal implants or residual disease after primary surgery and tumor debulking (Morice, 2012; Seidman, 2000).

Due to the indolent nature of these tumors, symptomatic recurrence often follows years or even decades after the initial

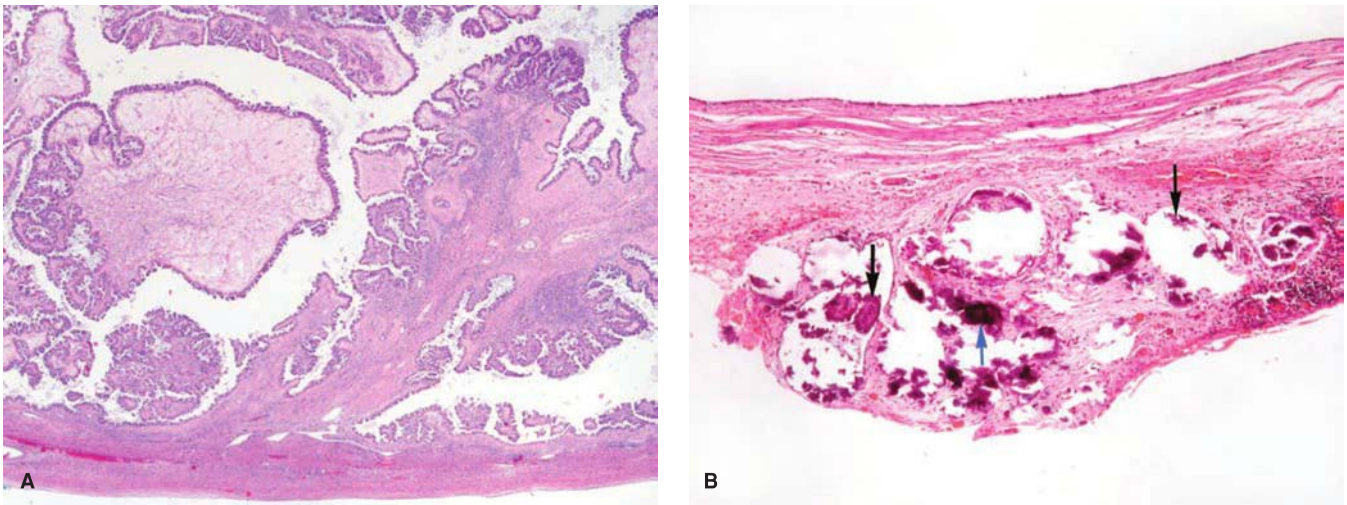

FIGURE 35-2 A. Serous borderline tumor/atypical proliferative serous tumor. These tumors are noninvasive tumors characterized by branching stromal papillae lined by cuboidal to columnar nonmucinous cells with minimal cytologic atypia. Papillae show a varying degree of epithelial proliferation, indicated by stratification or tufting. (Reproduced with permission from Dr. Kelley Carrick.) **B.** A noninvasive implant of a serous borderline tumor. Bland proliferative serous-type epithelium (*black arrows*) and associated psammoma bodies (*blue arrow*) adhere to the underlying tissue but do not invade it. The proliferative serous epithelium forms small clusters and papillary structures. Psammoma bodies, concentrically lamellated calcifications, are often associated with benign or malignant ovarian serous tumors. The artifactual shattering seen here is due to the calcified psammoma bodies. (Reproduced with permission from Dr. Raheela Ashfaq.)

diagnosis (Silva, 2006). Approximately 70 percent of relapses show only LMP histology. Malignant transformation into an invasive ovarian cancer develops in the other 30 percent. Most of these are low-grade carcinomas, but approximately one third will have high-grade features, which adversely affects prognosis (du Bois, 2013; Harter, 2014). As in primary ovarian LMP tumors, complete surgical excision is the most effective therapy for recurrent disease (Crane, 2015). Cytotoxic chemotherapy is reserved for patients with invasive features, but low-grade tumors tend to be particularly resistant to standard agents. Hormonal therapy is increasingly used with good results and much less toxicity (Gershenson, 2017; Tang, 2019).

EPITHELIAL OVARIAN CANCER

Pathogenesis

At least two distinct, albeit controversial, tumorigenic pathways account for epithelial ovarian cancer's heterogeneity (Table 35-4) (Kurman, 2016). The first tumor group develops either from benign extraovarian lesions that implant on the ovary and subsequently undergo malignant transformation or from a portion of the ovarian surface epithelium that becomes entrapped within the ovarian cortex. This trapped cortical inclusion cyst undergoes müllerian metaplasia and is exposed to hormone and inflammatory stimuli that induce DNA damage and mutations. These mutations can thereby transform the metaplastic cyst into a mucinous, endometrioid, or low-grade serous carcinoma (Levanon, 2008). These tumors usually present as large, unilateral, cystic neoplasms without ascites. They are clinically indolent, are diagnosed early, and account for only 10 percent of ovarian cancer deaths. Shown in Table 35-4, this first group is divided into endometriosis-associated tumors, low-grade serous carcinomas, and mucinous carcinomas plus malignant Brenner tumors (Kurman, 2016).

The second, more common group invariably contains high-grade serous carcinomas arising from the fallopian tube fimbria. This group was formerly thought to arise spontaneously on the ovarian or peritoneal surface. Although the neoplastic transformational trigger of the fallopian tube cells is unclear, serous tubal intraepithelial carcinoma (STIC) is a precursor condition (Fig. 35-3). STIC develops several years before initiation of ovarian carcinoma, yet metastases follow rapidly thereafter (Labidi-Galy, 2017).

TABLE 35-4. Dualistic Model of Ovarian Cancer Genesis

TYPE I				TYPE II
Endometriosis	**Fallopian Tube**	**Germ Cell**	**Transitional Cell**	**Fallopian Tube**
Endometrioid Clear cell Seromucinous	Low-grade serous	Mucinous	Mucinous Brenner tumor	High-grade serous Histologic subtype: Usual type Transitional cell type Carcinosarcoma Undifferentiated carcinoma

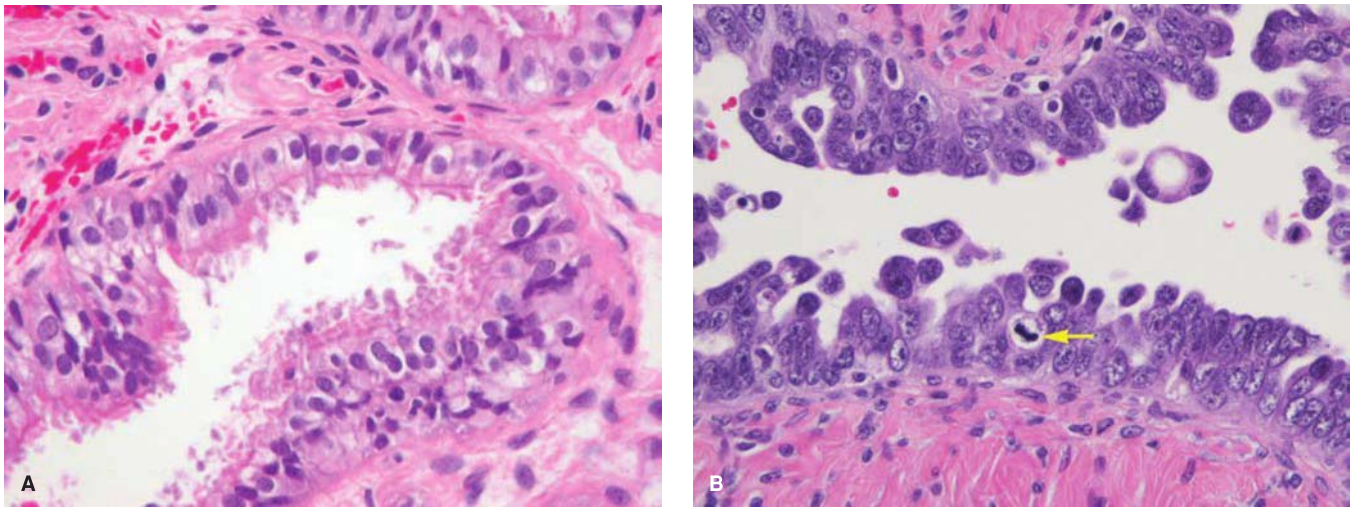

FIGURE 35-3 A. Normal fallopian tube epithelium is composed of three cell types—columnar ciliated cells, nonciliated secretory (peg) cells, and intercalary cells. **B.** Serous tubal intraepithelial carcinoma (STIC). The cells of serous carcinoma lining this fallopian tube are markedly atypical, with nuclear pleomorphism, chromatin coarseness, loss of nuclear polarity, increased nuclear/cytoplasmic ratio, and mitotic activity (*arrow*). Epithelial proliferation/tufting and loss of cell cohesion lead to cell shedding into the tubal lumen. (Reproduced with permission from Dr. Kelley Carrick.)

Approximately half of these tumors are characterized by mutations in genes involved in the HR pathway of DNA repair, especially *BRCA1* and *BRCA2* (Kroeger, 2017). Most of these mutations result from an inherited predisposition. For example, women born with a *BRCA* mutation require only one "hit" to the other normal copy (allele) to "knock out" the *BRCA* tumor-suppressor gene product. As a result, BRCA-related cancers develop approximately 15 years before sporadic cases. Alternatively, the tumor itself may develop a somatic mutation that deactivates BRCA's tumor suppression. As a result, current practice is for a woman to undergo both germline and tumor testing for *BRCA* and HR deficiency gene mutations.

High-grade serous tumors are aggressive, are diagnosed at advanced stages more than three quarters of the time, and display a greater volume of extraovarian disease and significant ascites. These tumors account for 90 percent of ovarian cancer deaths (Kurman, 2016).

Diagnosis

Symptoms and Physical Findings

Ovarian cancer is typically portrayed as a "silent" killer that lacks appreciable early signs or symptoms. This is a misconception. Actually, patients often are symptomatic for several months before the diagnosis, even with early-stage disease (Goff, 2000). The difficulty is distinguishing these symptoms from those that normally occur in women.

In general, persistent symptoms that are more severe or frequent than expected and have a recent onset merit further diagnostic investigation. Commonly, increased abdominal size, bloating, urinary urgency, and pelvic pain are reported. Fatigue, indigestion, inability to eat normally, constipation, and back pain also may be noted (Goff, 2004). Abnormal vaginal bleeding is rare. Occasionally, patients present with nausea, vomiting, and a partial bowel obstruction if carcinomatosis is particularly widespread. Unfortunately, women and clinicians often attribute most symptoms to menopause, aging, dietary changes, stress, depression, or functional bowel problems, and thus diagnosis is delayed.

A pelvic or abdominopelvic mass is palpable in most patients with ovarian cancer during bimanual evaluation. Malignant tumors tend to be solid, nodular, and fixed, but no classic findings reliably distinguish these growths from benign tumors. Paradoxically, a huge mass filling the pelvis and abdomen more often represents a benign or borderline tumor. To aid surgical planning, a rectovaginal examination also is performed. For example, a woman with tumor involving the rectovaginal septum may need to be positioned in dorsal lithotomy to perform a low anterior colon resection.

An abdominal fluid wave or, less commonly, flank bulging suggests significant ascites. In a woman with a pelvic mass and ascites, the diagnosis is ovarian cancer until proven otherwise. However, ascites without an identifiable pelvic mass suggests the possibility of cirrhosis or primary malignancies from the stomach or pancreas. In advanced disease, examination of the upper abdomen usually reveals a central mass signifying omental caking. Although rare, an umbilical nodule, the "Sister Mary Joseph sign," reflects spread from an intraabdominal malignancy.

Auscultation of the chest also is important, since patients with malignant pleural effusions may not be overtly symptomatic. The remainder of the examination includes palpation of the peripheral nodes in addition to a general physical assessment.

Laboratory Testing

A routine complete blood count and metabolic panel often demonstrates a few characteristic features. Of affected women, 20 to 25 percent will present with thrombocytosis (platelet count $>400 \times 10^9$/L) (Li, 2004). Malignant ovarian cells releasing cytokines are believed to raise platelet production rates. Hyponatremia, typically ranging between 125 and 130 mEq/L,

is another common finding. In these patients, tumor secretion of a vasopressin-like substance can cause a clinical picture suggesting a syndrome of inappropriate antidiuretic hormone (SIADH).

The serum CA125 level is integral to epithelial ovarian cancer management. In 90 percent of women presenting with malignant nonmucinous tumors, CA125 levels are elevated. However, there are caveats to bear in mind during adnexal mass evaluation. Half of stage I ovarian cancers will have a normal CA125 measurement (false negative). Also, an elevated value (false positive) may be associated with various common benign indications such as pelvic inflammatory disease, endometriosis, leiomyomas, pregnancy, and even menstruation. Thus, in postmenopausal women with a pelvic mass, a CA125 measurement may better predict a higher likelihood of malignancy (Table 10-1, p. 220) (Im, 2005).

Another marker, the human epididymal protein 4 (HE4) tumor marker, is approved by the U.S. Food and Drug Administration (FDA), along with CA125, when used in the Risk of Ovarian Malignancy Algorithm (ROMA). This algorithm predicts the likelihood of finding malignancy at surgery in a woman with an adnexal mass. The ROMA score is derived from the results of both blood tests plus menopausal status (Moore, 2009, 2010).

OVA1 is another biomarker blood test panel that may be used for the preoperative triage of women with an identified ovarian mass when surgery is planned (Ueland, 2011; Ware Miller, 2011). Scores ≥5.0 in premenopausal and scores ≥4.4 in postmenopausal women suggest a need for gynecologic oncologist consultation. Importantly, this test is not a screening tool and is reserved for those with a known surgical mass to aid preoperative triage (Zhang, 2010).

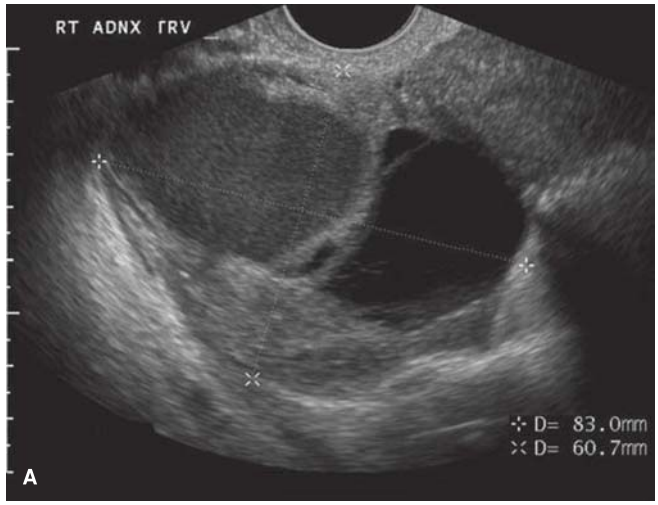
Validation studies evaluating ROMA and OVA1 are limited, and their role in preoperative triage is yet to be clearly defined. As a result, they are not necessarily recommended for determining the status of an identified but undiagnosed pelvic mass (Armstrong, 2019).

Similarly, the risk of malignancy index (RMI) algorithm factors menopausal status, CA125 serum level, and sonographic score. This last element is derived from ovarian appearance, and presence of ascites or intraabdominal metastases (Jacobs, 1990; Karlsen, 2012).

When a mucinous ovarian tumor is suspected or found, cancer antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA) serum tumor markers may be better indicators. Markers that more suitably reflect germ cell tumors or sex cord–stromal tumors are found in Tables 36-1 and 36-4 (p. 757).

Imaging

Transvaginal sonography is typically the most useful imaging test to differentiate benign tumors and early-stage ovarian cancers (Chap. 10, p. 221). In general, malignant tumors are multiloculated, solid or echogenic, and large (>5 cm), and they have thick septa with areas of nodularity (Fig. 35-4A). Other features may include papillary projections or neovascularization—demonstrated by adding color Doppler (Figs. 35-4B and 35-4C). Although several presumptive imaging models have been described to help distinguish benign masses from ovarian



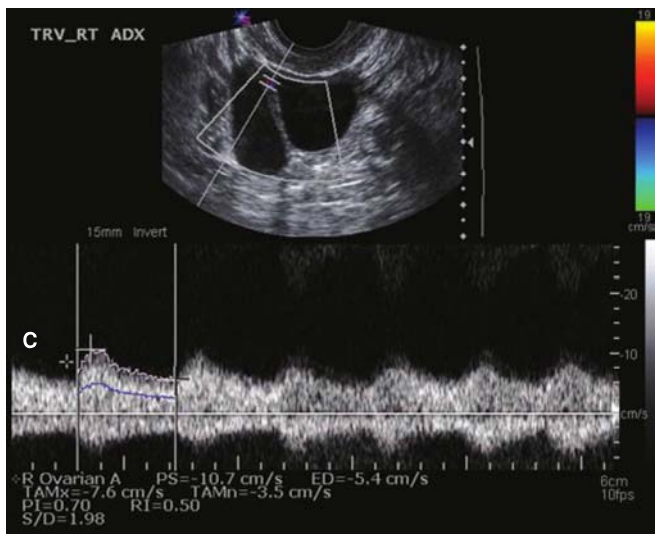


FIGURE 35-4 Sonograms of an ovarian cyst. **A.** Transvaginal sonogram depicts a complex ovarian mass. Cystic and solid components and a thick intracystic septum are seen. These findings raise clinical concern for malignancy. **B.** Color Doppler transvaginal sonogram shows neovascularization within this ovarian tumor. **C.** Transvaginal Doppler study of ovarian mass vessels reveals decreased impedance. cancers preoperatively, none has been universally implemented (Elder, 2014; Suh-Burgmann, 2018).

In patients with advanced disease, sonography is less helpful. The pelvic sonogram may be particularly difficult to interpret if a large mass encompasses the uterus, adnexa, and surrounding structures. Ascites, if present, is easily detected, but in general, abdominal sonography has limited use.

Of *radiographic tests*, patients with suspected ovarian cancer should have a chest radiograph to detect pulmonary effusions or, infrequently, pulmonary metastases. Rarely, a barium enema is clinically helpful in excluding diverticular disease or colon cancer or in identifying ovarian cancer involvement of the rectosigmoid.

CT scanning has a primary role in treatment planning for women with advanced ovarian cancer. Preoperatively, implants in the liver, retroperitoneum, omentum, or other intraabdominal sites are detected to thereby guide surgical cytoreduction or demonstrate obviously unresectable disease (Fig. 35-5) (Suidan, 2014). However, CT is not particularly reliable in detecting intraperitoneal disease smaller than 1 to 2 cm in diameter. Moreover, CT scanning accuracy is poor for differentiating a benign ovarian mass from a malignant tumor when disease is limited to the pelvis. In these cases, transvaginal sonography is superior. Other radiologic studies such as magnetic resonance (MR) imaging, bone scans, and positron emission tomography (PET) in general provide limited additional information preoperatively.

Paracentesis

A woman with a pelvic mass and ascites usually can be assumed to have ovarian cancer until surgically proved otherwise. Thus, few patients require diagnostic paracentesis. Moreover, this procedure is typically avoided diagnostically as cytologic results are often nonspecific and abdominal wall metastases may form at the needle entry site (Kruitwagen, 1996). However, paracentesis may be indicated for those with ascites in the *absence* of a pelvic mass.

Aside from diagnosis, paracentesis also may relieve volume-related symptoms in those with large accumulations. This may be done at the bedside, using connector tubing and vacuum bottles, or completed by an interventional radiologist. Relative dehydration is common afterward and manifest by thirst, oliguria, and short-term creatinine level rise. These all correct with normal oral intake.

Role of the Generalist

Using the currently available diagnostic modalities, clinicians often face tremendous difficulty in distinguishing benign from malignant. However, ascites or evidence of metastases should prompt consideration of consultation with an oncologist (American College of Obstetricians and Gynecologists, 2016, 2017b). Additionally, premenopausal women with elevated CA125 levels (>200 U/mL) or an OVA1 score ≥5.0 are at higher risk. Similarly, postmenopausal women with any CA125 level elevation or an OVA1 score ≥4.4 are concerning.

Ideally, for patients with suspicious adnexal masses, surgery is performed in a hospital with a pathologist able to reliably interpret an intraoperative frozen section. At minimum, samples for peritoneal cytology are obtained when the abdomen is entered. The mass is removed intact through an incision that permits thorough staging and resection of possible metastatic sites. Alternatively, the ovarian mass and adjacent tube may be detached laparoscopically or robotically, placed within a bag, brought to the abdominal wall trocar site, and removed by contained tissue extraction without intraabdominal spill.

If malignancy is diagnosed, surgical staging is completed. However, in a study of more than 10,000 women with ovarian cancer, almost half of those with early-stage disease did

not undergo the recommended surgical procedures (Goff, 2006). Surgeons should be prepared to appropriately stage and potentially debulk ovarian cancer or have a gynecologic oncologist immediately available. This type of careful planning achieves the best surgical results and improves survival rates (Earle, 2006; Engelen, 2006; Mercado, 2010). Moreover, since broader resources are usually available, patients cared for at high-volume hospitals also tend to have better outcomes (Bristow, 2010).

For women with malignancy identified only postoperatively or intraoperatively and without adequate staging, management will vary. Women with suspected early-stage disease may be restaged laparoscopically or robotically. Those with advanced disease may undergo a second laparotomy to achieve optimal tumor debulking (Grabowski, 2012). However, if extensive disease is found at the initial surgery, chemotherapy may be selected first and followed later by interval cytoreduction.

At some point during postoperative surveillance, many women with early-stage disease, depending on the diagnosis, will return to their referring physician. Monitoring for relapse is often coordinated between the gynecologic oncologist and generalist in obstetrics and gynecology, especially if no chemotherapy is required following surgery.

Pathology

Although epithelial ovarian cancer is often considered a single entity, the different histologic types vary in their behavior (Table 35-5) (Kurman, 2014). Sometimes, two or more cell types are mixed. Within each histologic type, tumors are further categorized as benign, borderline (low malignant potential), or malignant.

Mainly in early-stage disease, grade is an important prognostic factor that affects treatment planning (Armstrong, 2019). Unfortunately, no grading system for epithelial ovarian carcinoma is universally accepted. Instead, numerous different schemes, most based on architecture and/or nuclear pleomorphism, are currently used. In general, tumors are classified as grade 1 (well differentiated), grade 2 (moderately differentiated), and grade 3 (poorly differentiated) (Pecorelli, 1999).

TABLE 35-5. World Health Organization Histological Classification of Ovarian Carcinoma

Serous adenocarcinoma
Mucinous adenocarcinoma
Endometrioid adenocarcinoma
Clear cell adenocarcinoma
Malignant Brenner tumor
Mixed epithelial and mesenchymal
Adenocarcinoma
Carcinosarcoma
Squamous cell carcinoma
Mixed carcinoma
Undifferentiated carcinoma
Small cell carcinoma

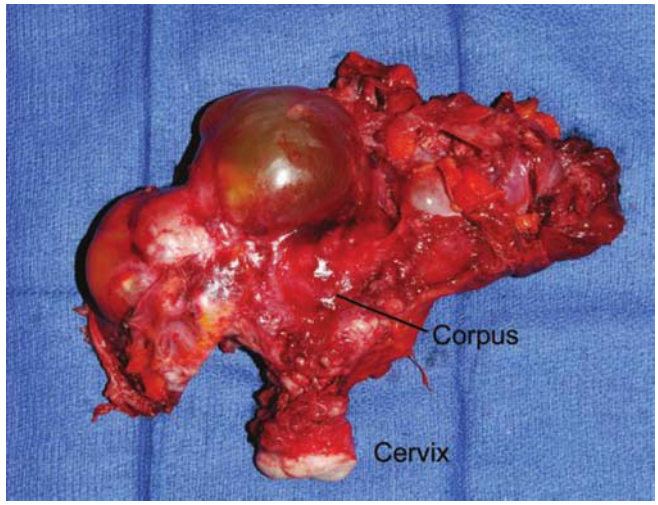

FIGURE 35-6 Hysterectomy specimen and bilateral adnexa encompassed by serous adenocarcinoma of the ovary.

Grossly, no features distinguish the different types of epithelial ovarian cancer. In general, each has solid and cystic areas of varying sizes (Fig. 35-6).

Serous Tumors

More than 50 percent of all epithelial ovarian cancers have serous histology. Microscopically, in well-differentiated tumors, cells may resemble fallopian tube epithelium, whereas in poorly differentiated tumors, anaplastic cells with severe nuclear atypia predominate (Fig. 35-7). During frozen section analysis, psammoma bodies are essentially pathognomonic of an ovarian-type serous carcinoma. These tumors often contain other cell types as a minor component (<10 percent) that may cause diagnostic problems but do not influence outcome (Lee, 2003).

Endometrioid Tumors

Endometrioid adenocarcinomas compose 15 to 20 percent of epithelial ovarian cancers and are the second most common histologic type (Fig. 35-8). The lower frequency results largely because poorly differentiated endometrioid and serous tumors cannot be easily distinguished and such cases are usually classified as serous. As a result, well-differentiated endometrioid tumors are proportionally more common, which may also explain their overall relatively good prognosis.

In 15 to 20 percent of cases, uterine endometrial adenocarcinoma coexists. This is usually regarded as a synchronous tumor, but metastasis from one site to the other is difficult to exclude (Soliman, 2004). A müllerian "field effect" is theorized to account for these independently developing, histologically similar tumors. In addition, many such patients are noted to have pelvic endometriosis.

Carcinosarcoma

Malignant mixed müllerian tumor, now preferably termed *carcinosarcoma*, is a variant of poorly differentiated epithelial ovarian cancer that contains highly aggressive malignant epithelial and mesenchymal elements (Armstrong, 2019). It represents <1 percent of ovarian cancers, has a poorer prognosis than either high-grade serous or endometrioid tumors, and is

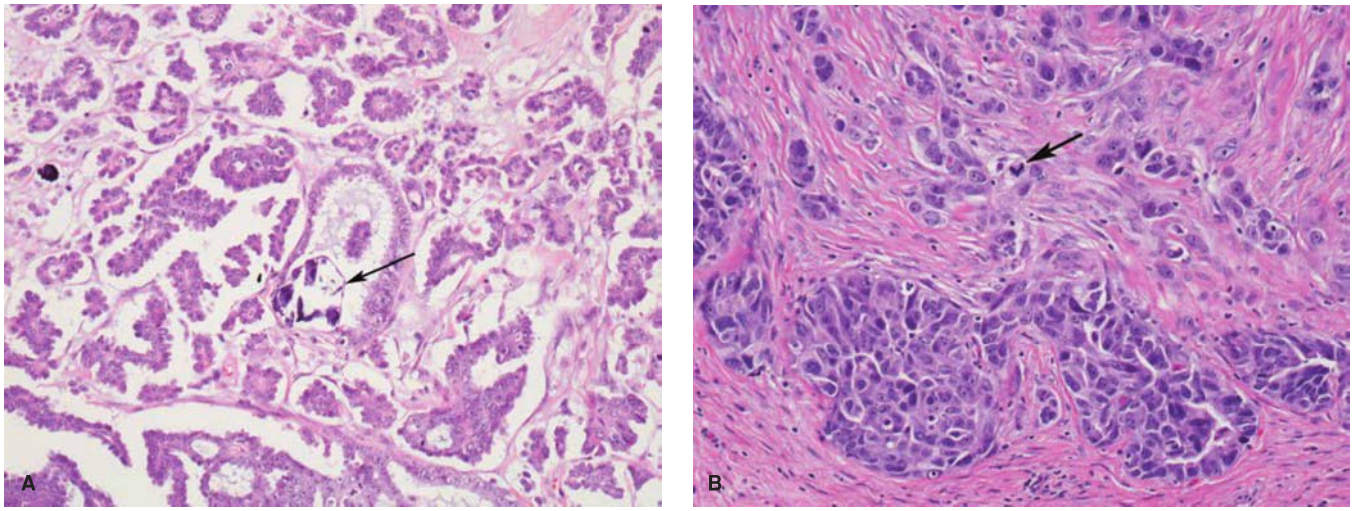

FIGURE 35-7 Tuboovarian serous carcinomas vary in their architecture, degree of nuclear pleomorphism, and mitotic rate. **A.** This low-grade serous carcinoma is characterized by well-differentiated architectural patterns (gland formation and papillae), mild to moderate nuclear atypia, and relatively low mitotic rate. Here, mildly atypical tumor cells are arranged primarily in fine papillae, with focal gland formation. An associated psammoma body is seen in the center (*arrow*). **B.** High-grade serous carcinoma has high-grade nuclear atypia with increased nuclear pleomorphism, chromatin abnormalities, and nucleolar prominence. The mitotic rate is typically high, and architectural patterns may be less well-differentiated. Tumor invades in cords and glands with ill-defined intraluminal papillation. An abnormal mitosis is seen (*arrow*). (Reproduced with permission from Dr. Kelley Carrick.)

histologically similar to uterine carcinosarcoma (Berton-Rigaud, 2014).

Mucinous Tumors
